Abstract

Shared ecological conditions encountered by species that colonize islands often lead to the evolution of convergent phenotypes, commonly referred to as the "island syndrome". Reduced immune functions have been previously proposed to be part of this syndrome, as a consequence of the reduced diversity of pathogens on island ecosystems. According to this hypothesis, immune genes are expected to exhibit genomic signatures of relaxed selection pressure in island species. In this study, we used comparative genomic methods to study immune genes in island species (N = 20) and their mainland relatives (N = 14). We gathered public data as well as generated new data on innate (TLR: Toll-Like Receptors, BD: Beta Defensins) and acquired immune genes (MHC: Major Histocompatibility Complex classes I and II), but also on hundreds of genes with various immune fonctions. As a control, we used a set of 97 genes, not known as involved in immune functions based on the literature, to account the increased drift effects for the lower effective population sizes in island species. We used synonymous and non-synonymous variations to estimate the selection pressure acting on immune genes. BDs and TLRs have higher ratios of non-synonymous over synonymous polymorphisms (Pn/Ps) than randomly selected control genes suggesting that they evolve under a different selection regime than non-immune related genes. However, simulations analyses show that this is unlikely to be explained by ongoing positive selection or balancing selection. For the MHC evolving under balancing selection, we used simulation to estimate the impact of population size variation. We found a significant effect of drift on immune genes of island species leading to a reduction in genetic diversity and efficacy of selection. However, the intensity of relaxed selection was not significantly different from control genes, except for MHC class II genes. These genes exhibit a significantly higher level of non-synonymous loss of polymorphism than expected assuming only drift and an evolution under frequency dependent selection, possibly due to a reduction of extracellular parasite communities on islands. Overall, our results showed that demographic effects lead to a decrease in the immune functions of island species, but the relaxed selection caused by a reduced parasite pressure may only occur in some immune genes categories.

Keywords: genetic drift, island evolution, immunity, Toll-Like Receptors, Beta-Defensins, major histocompatibility complex, molecular evolution, population genomics

Introduction

Island colonizers face new communities of competitors, predators and parasites in a small area with limited resources, which generally result in high extinction rates of colonizers (Losos and Ricklefs, 2009). Oceanic island faunas are characterized by a low species richness, coupled with high population densities for each species (MacArthur and Wilson, 1967; Warren et al., 2015) - which translates in communities with, on average, low levels of inter-specific interaction and high levels of intra-specific competition (but see Rando et al., 2010 for an example of character displacement due to competition among island finch species). These shared island characteristics are thought to underlie the evolution of convergent phenotypes, in what is called the 'island syndrome' (Baeckens and Van Damme, 2020). Convergence has been documented in multiple traits, such as size modification (dwarfism or gigantism; Lomolino, 2005), reduction of dispersal (Baeckens and Van Damme, 2020) shift towards K life history strategies (Boyce, 1984; Covas, 2012; MacArthur and Wilson, 1967), evolution of generalist traits (Blondel, 2000; Warren et al., 2015), or changes in colour and acoustic signals (Doutrelant et al., 2016; Grant, 1965).

Reduced immune function has also been hypothesized as an island syndrome trait, directly linked to reduced parasite pressure on islands (Lobato et al., 2017; Matson and Beadell, 2010; Wikelski et al., 2004). Island parasite communities are i) less diverse (Beadell et al., 2006; Illera et al., 2015; Loiseau et al., 2017; Maria et al., 2009; Pérez-Rodríguez et al., 2013), and ii) could be less virulent due to the expansion of the ecological niche expected by the theory of island biogeography. In fact, island parasites are generally more generalists than their mainland counterparts, which could lead to a reduced virulence due to the trade-off between replication capacity and resistance against host immune defenses (Garamszegi, 2006; Hochberg and Møller, 2001; Pérez-Rodríguez et al., 2013). Overall, a reduction of parasitic pressure should lead to a weakening of the immune system due to the costs of maintaining efficient immune functions (Lindström et al., 2004; Matson and Beadell, 2010; Wikelski et al., 2004). Such reduction may have important implications for the ability of these populations to resist or tolerate novel pathogens. The introduction of avian malaria in the Hawaiian archipelago, and the subsequent extinctions and population declines of many endemic species is the most emblematic example (Van Riper III et al., 1986; Wikelski et al., 2004).

Immunological parameters, such as blood leukocyte concentration, antibodies or other immune proteins (e.g. haptoglobin), hemolysis, and hemagglutination (Lee et al., 2006; Matson and

Beadell, 2010) may serve as proxies to determine population immune functions. To date, the majority of studies that focused on island avifauna have found ambiguous results, with either no support for a reduced immune response on island species (Beadell et al., 2007; Matson, 2006), or contrasted results, such as a lower humoral component (total immunoglobulins) on islands, but a similar innate component (haptoglobin levels) between island and mainland species (Lobato et al., 2017). The use of immune parameters as proxies of immune function is fraught with difficulties (Lobato et al., 2017). The study of molecular evolution of immune genes therefore represents an alternative strategy to tackle this question. However, it is necessary to distinguish neutral effects, the demographic effects resulting from island colonization, from selective ones, the potential relaxation of selection pressures due to the changes in the pathogen community.

First, the bottleneck experienced by species during island colonization leads to a decrease in genetic variability (Frankham, 1997). A reduced genetic diversity at loci involved in immunity should have a direct implication on immune functions (Hale and Briskie, 2007 but see ; Hawley et al., 2005; Spurgin et al., 2011). Second, small population sizes increase genetic drift, which may counteract the effect of natural selection on weakly deleterious mutations (Ohta, 1992). Several recent studies found a greater load of deleterious mutations in island species (Kutschera et al., 2020; Leroy et al., 2021b; Loire et al., 2013; Robinson et al., 2016; Rogers and Slatkin, 2017). Finally, it is necessary to differentiate genes involved in the innate versus the acquired immune response. The innate immune response is the first line of defense and is composed of phagocytes, macrophages and dendritic cells. These cells allow non-specific recognition of pathogens (Akira, 2003; Alberts et al., 2002). For example, Toll-Like Receptors (TLR; transmembrane proteins) trigger a chain reaction leading to the production of various substances, including antimicrobial peptides such as beta-defensins (BD) that have active properties in pathogen cell lysis (Velová et al., 2018). On the other hand, the acquired immune system allows a specific response, characterized by immune memory. Major Histocompatibility Complex (MHC) genes code for surface glycoproteins that bind to antigenic peptides, and present them to the cells of the immune system; class I and II genes ensure the presentation of a broad spectrum of intra- and extracellular-derived peptides, respectively (Klein, 1986). Although all these genes are directly involved in the identification and neutralization of pathogens, previous studies found that they evolve under different selection regimes: TLRs and BDs are under purifying selection which usually results in the selective

96 removal of deleterious alleles and stabilizing selection (Grueber et al., 2014; van Dijk et al.,
97 2008), whereas MHC genes are under balancing selection (Bernatchez and Landry, 2003).

98 Recent studies on birds (Gonzalez-Quevedo et al., 2015a, 2015b), amphibians (Belasen et al.,
99 2019), and lizards (Santonastaso et al., 2017) found that the demographic history of island
100 populations led to the loss of genetic variation at immune genes involved in pathogen
101 recognition, such as TLRs and MHC. For example, (Santonastaso et al., 2017) demonstrated
102 that the polymorphism pattern in MHC genes and microsatellites covary positively with island
103 area in *Podarcis* lizards, suggesting a dominant role for genetic drift in driving the evolution
104 of the MHC. Gonzalez-Quevedo, et al. (2015a) found a similar pattern comparing TLR and
105 microsatellite polymorphism in the Berthelot pipit, *Anthus berthelotii*, an endemic species from
106 Macaronesia, supporting a predominant role of genetic drift in TLR evolution. However, these
107 studies did not explicitly test the hypothesis of a relaxed selection pressure on islands imposed
108 by an impoverished parasite community. All other things being equal, it is expected that the
109 polymorphism pattern of a coding sequence decreases with population size (Buffalo, 2021;
110 Leroy et al., 2021b). Therefore, a decrease in polymorphism with population size could not be
111 taken as a proof of a relaxation in the selection pressure.

112 Here, we study a dataset of 34 bird species (20 insular and 14 mainland species; Figure 1)
113 combining the 24 species of Leroy et al. (2021b) and 10 newly generated by targeted-capture
114 sequencing (Table 1). To be able to demonstrate a change in natural selection, a traditional
115 approach is to contrast polymorphism of synonymous sites (Ps) with polymorphism of non-
116 synonymous sites (Pn). Synonymous mutations refer to mutations that do not alter amino acid
117 sequences, whereas non-synonymous mutations do.

118 Following population genetic theory, in a diploid population, $Ps = 4\ Ne\ \mu$ and $Pn = 4\ Ne\ \mu\ f$,
119 where *Ne* is the effective population size, μ is the mutation rate and *f* is a function that integrates
120 the probability of an allele to segregate at a given frequency. *f* depends on the distribution of
121 the fitness effect (DFE) of mutations (Eyre-Walker and Keightley, 2007). This distribution
122 scales with *Ne* as the fitness effect is dependent on *Ne* multiplied by the coefficient of selection
123 *s* (Kimura, 1962). The nearly-neutral theory predicts that the DFE includes a large proportion
124 of mutations with a *Ne*s* close to 0 (Ohta, 1992). As a consequence, an increase of *Ne* will lead
125 to an increase of the fitness effect of weakly deleterious mutations, in such a way that these
126 mutations will be more easily removed from the population by natural selection, therefore
127 reducing Pn relative to Ps leading to a negative correlation between Pn/Ps and Ps (through Ne;

Welch et al., 2008). The presence of linked positively selected mutations does not change qualitatively this relationship (Castellano et al., 2018; Chen et al., 2020 and our simulations below).

Shifts in the parasitic community on islands are expected to have an impact on the ratio Pn/Ps of immune genes. However, the fixation probability depends on the product *Ne s*, and a variation in *Ne* is also expected to impact the efficacy of selection and thus the ratio Pn/Ps across the entire transcriptome, particularly in the presence of slightly deleterious mutations (Charlesworth and Eyre-Walker, 2008; Leroy et al., 2021b; Loire et al., 2013; Ohta, 1992). In addition, due to their lower population sizes, island birds compared to continental species exhibit a genome-wide reduction in genetic diversity and efficacy of selection (Kutschera et al., 2020; Leroy et al., 2021b). Therefore, we expect a similar reduction in immune genes diversity even without any change in the parasite pressure.

To disentangle the effect of population size from a change in parasite pressure and estimate the impact of demography on the efficacy of selection, we randomly selected protein-coding genes (i.e., control genes) involved in various biological functions (Fijarczyk et al., 2016; Leroy et al., 2021b). The selection pressure acting on the randomly selected control genes is expected to be similar between island and mainland bird species. Therefore, the variation of Pn/Ps of the control genes is only dependent on the variation of *Ne*. In contrast, if a reduced parasite pressure on islands directly impacts the evolution of immune genes, the Pn/Ps of immune genes is expected to show a larger variation between island and continental species than the control genes. More specifically, for genes under purifying selection, non-synonymous weakly deleterious mutations, normally eliminated under strong selection, would be maintained, leading to an increase of Pn/Ps. By contrast, for genes under balancing selection, non-synonymous advantageous mutations, normally maintained in the polymorphism under strong selection, would be fixed or eliminated leading to a decrease of Pn/Ps (Figure 2).

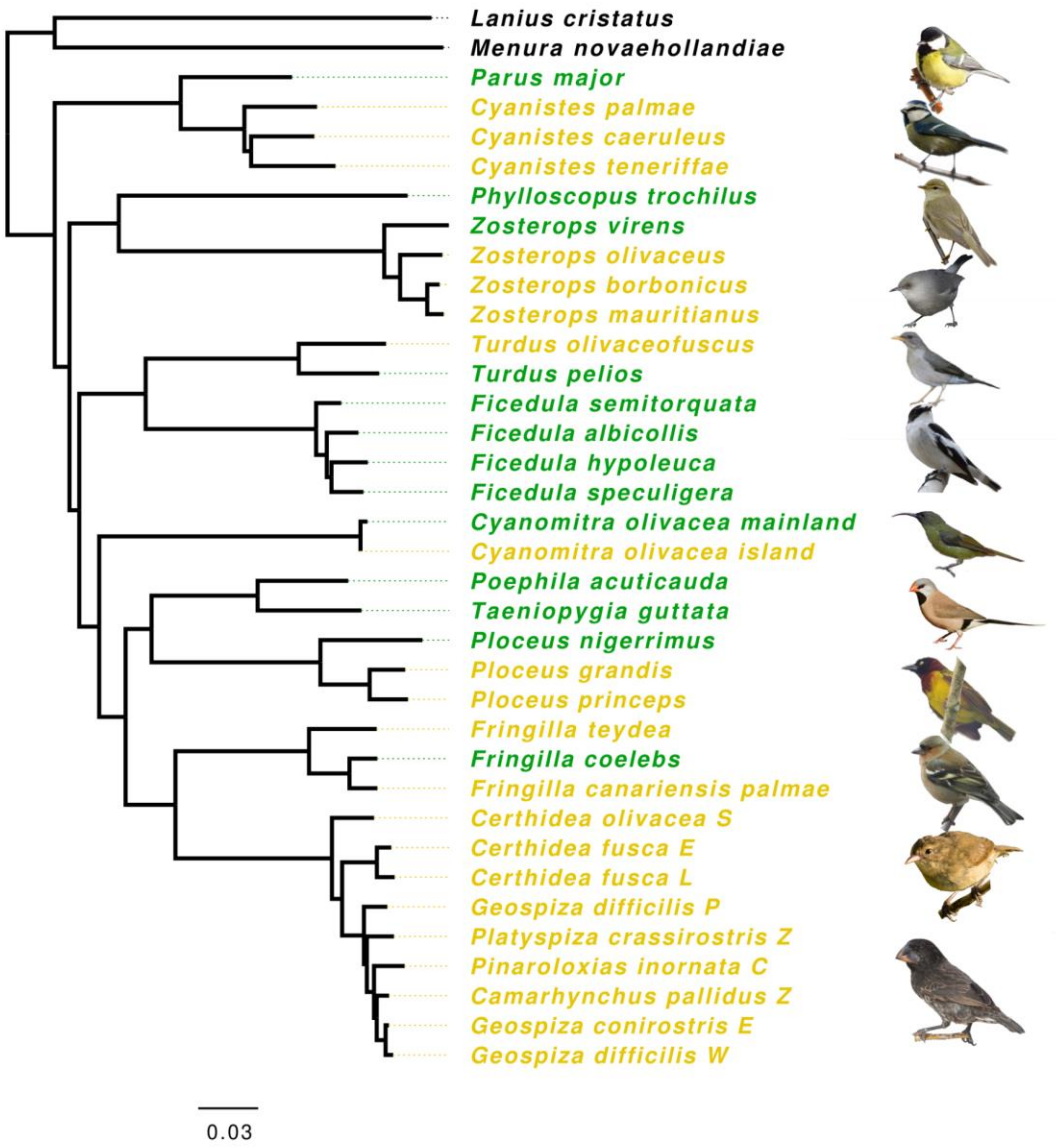

Figure 1: Phylogeny based on mitochondrial genes of species from the dataset reconstructed by maximum likelihood method (IQTREE model GTR+Gamma). Species names in yellow indicate island species, and in green, mainland species. Ultrafast bootstrap values are provided in the supplementary methods. Some relationships are poorly supported. Bird representations are not to scale. Vos (iNaturalist.org); M. Gabrielli (*Zosterops borbonicus*).

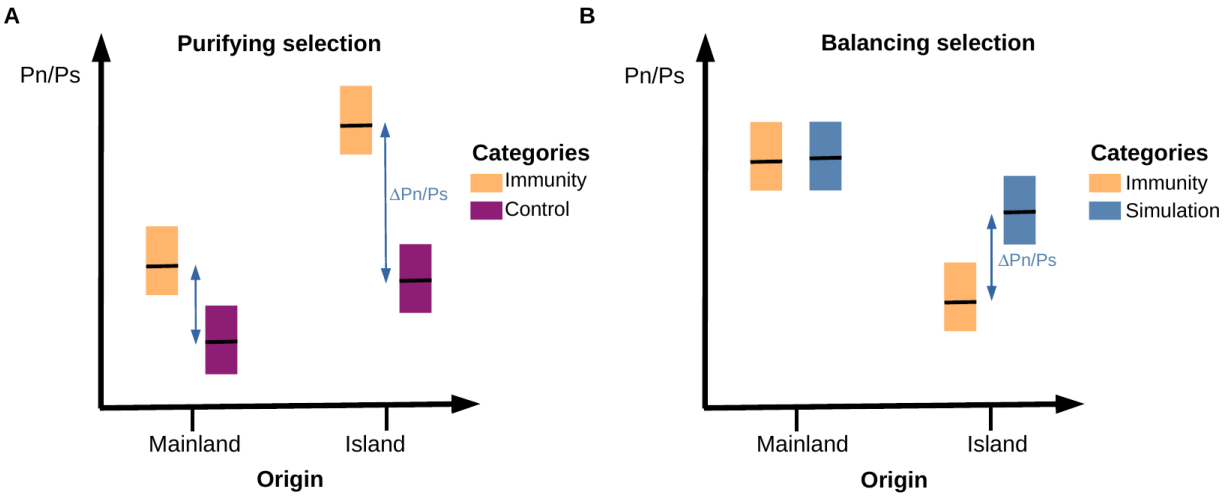

Figure 2: Conceptual diagram showing the expected results under the hypothesis of a relaxation in the selection pressure of the immune genes in island species due to a change in the parasitic community. A) Genes evolving under purifying selection where control genes are randomly selected protein-coding genes. B) Genes evolving under balancing selection where controls are obtained from SLiM simulations of genes evolving under the same balancing selection but different population size. Under the hypothesis of a relaxed selection as a consequence of the reduced diversity of pathogens on island ecosystems, the difference in Pn/Ps between categories (ΔPn/Ps) is expected to be different between species' origin, leading to a statistical interaction between gene categories and origin.

Methods

Dataset

Alignments of Coding DNA Sequences (CDS) of individuals from 24 species were obtained from Leroy et al. (2021b). In addition, data for ten other species (six and four from islands and mainland, respectively) were newly generated for this study by targeted-capture sequencing. Blood samples and subsequent DNA extractions were performed by different research teams. The complete dataset consisted of 34 bird species (20 and 14 insular and mainland species respectively; Table 1; Figure 1). We filtered alignments in order to retain only files containing a minimum of five diploid individuals per site (Table 1).

Sequence enrichment was performed using MYBaits Custom Target Capture Kit targeting 21 immune genes: 10 Toll-Like receptors (TLR), 9 Beta Defensins (BD), 2 Major Histocompatibility Complex (MHC) and 97 control genes (see below). We followed the manufacturer's protocol (Rohland and Reich, 2012). Illumina high-throughput sequencing using a paired-end 150 bp strategy was performed by Novogene (Cambridge, UK).

200 *Newly generated draft genome sequence*

201 We generated whole genome sequences at moderate coverage (~40X) for *Turdus pelios*,
202 *Ploceus cucullatus* and *Cyanomitra olivacea* (from Gabon). Library preparation from blood

DNA samples and Illumina high-throughput sequencing using a paired-end 150 bp strategy were performed at Novogene (Cambridge, UK). Raw reads were cleaned using FastP (vers. 0.20.0; Chen et al., 2018). Genomes assemblies were performed using SOAPdenovo (vers. 2.04) and Gapcloser (v1.10) (Luo et al., 2012) with parameters "-d 1 -D 2" and a kmers size of 33. Protein annotation was performed by homology detection using genBlastG (She et al., 2011; http://genome.sfu.ca/genblast/download.html) and the transcriptome of the collared flycatcher (*Ficedula albicollis*; assembly FicAlb1.5; Ellegren et al., 2012) as reference.

Capture data processing

Reads from targeted-capture sequencing were cleaned with FastP (vers. 0.20.0; Chen et al., 2018). Reads of each individual were mapped respectively to the nearest available reference genomes using bwa mem (vers. 0.7.17; Li, 2013; Table 1), with default parameters. Samtools (vers. 1.3.1; Li et al., 2009) and Picard (vers. 1.4.2; Picard Toolkit 2019) were used to convert the mapping files, order and index reads according to their position on the chromosomes (or scaffolds) of the reference genomes or on the draft genomes generated in this study for *Ploceus*, *Cyanomitra* and *Turdus*. Duplicate reads were marked using MarkDuplicates (vers. 1.140; Picard Toolkit 2019). SNP calling was performed with Freebayes (vers. 1.3.1; Garrison and Marth, 2012). Freebayes output file (VCF file) was converted to a fasta file by filtering out sites with a minimum quality of 40 and a sequencing depth between 10 and 1000X (sites outside these thresholds were treated as missing data, i.e., 'N'). CDS were then extracted from the alignments using the coordinates of the annotations (gff files). CDS were aligned using MACSE (vers. 2.03; Ranwez et al., 2011) to prevent frameshift mutation errors and GNU-parallel (Tange, 2018) was used to parallelise the computation.

Selection and identification of immune and control genes

We defined several groups of immune genes to compare with the control genes. The control group consisted of 97 protein-coding genes randomly selected in the genome of *Zosterops borbonicus* (Leroy et al., 2021a). These control genes allowed the estimation of the average selection pressure that a gene, not involved in the immune response, undergoes in the genome. These genes are single copy (absence of paralogue) and have a variable GC content representative of the whole transcriptome.

For the immune genes, we selected three sets of genes from i) a limited set of genes (Core Group) where functions are unambiguously related to immunity, and ii) two larger sets of genes (Database-group & Sma3s-group), obtained through an automatic annotation pipeline.

The Core Group included MHC class I and class II genes, 10 Toll-Like Receptors (TLRs; Velová et al., 2018) and 9 Beta Defensins (BD; Chapman et al., 2016). The Database group included genes identified by Immunome Knowledge Base (Ortutay and Vihinen, 2009, http://structure.bmc.lu.se/idbase/IKB/; last access 04/02/2020) and InnateDB (Breuer et al., 2013, http://www.innatedb.com ; last access 04/02/2020). We also added a set of genes for which the genetic ontology indicated a role in immune functions. To do so, we used the chicken (*Gallus gallus*) annotation (assembly GRCg6a downloaded from Ensembl database in March 2020; https://www.ensembl.org/). We identified genes with the terms "immun*" or "pathogen*" in their Gene Ontology identifiers description (directory obtained from http://geneontology.org/). This set included 2605 genes considered to be involved in immunity, although some may be only indirectly involved in immunity or have a small impact on immune functions. Finally, the third set of genes (Sma3s-group) has been built up through the Sma3s-group program (vers. 2; Munoz-Mérida et al., 2014). This program annotated sequences in order to be associated with biological functions through gene ontology identifiers. The annotation of the genome of *F. albicollis* allowed us to identify 3136 genes associated with the genetic ontology "immune system processes". Like for the Database group, this set may include genes with various functions in the immune response. It should be noted that Sma3s-group and Database-group are not mutually exclusive, and some genes are present in both groups. An analysis was performed to identify and exclude genes under balancing selection from Database-group and Sma3s-group sets using BetaScan (vers. 2; Siewert and Voight, 2020), due to the potentially antagonistic responses of these genes. Very few genes (only 2 and 3 genes from Database-group and Sma3s-group sets) were identified and removed from the analysis (see Detection of genes under balancing selection in Supplementary Methods).

Test for contamination and population structure

We use the program CroCo (vers. 1.1; Simion et al., 2018) to identify candidates for cross-species contamination (see supplementary materials for details). Overall, we did not detect a clear case of cross-species contamination in our dataset (Figure S1). Contigs identified as potential contamination always involve a pair of species belonging to the same genus. In this

case, contamination could be difficult to identify due to the low genetic divergence between species.

For the newly sequenced species, we also performed PCA analyses on using allele frequencies of control genes. We use the function dudi.pca of adegenet R packages (Jombart and Ahmed, 2011). This analysis aims to check for population structure and to detect potentially problematic individuals (i.e., contaminated individuals). This analysis led to the exclusion of 4 individuals (*Ploceus princeps* P6-174; *P. grandis* ST10_094; *P. nigerrimus* G3_016; *C. teneriffae* TF57) for which we suspected contamination. Otherwise, no extra population structure was detected (Figure S2-S4).

Hidden paralogy

We compute the statistic Fis = 1-H0/He where H0 is the average number of heterozygous individual observed (H0 = #heterozygous / n ; where n is the sample size) and He is the expected number of heterozygous individuals at Hardy-Weinberg (HW) equilibrium (He = (n/(n-1) 2 * p * (1-p))*n where n is the sample size and p the allele frequency of a randomly chosen allele). Fis varies between -1 and 1 with positive value representing excess of homozygous individuals and negative value representing excess of heterozygous individuals compared to the HW proportions. Gene with high value of nucleotide diversity (Pi) and negative value of Fis could represent potential cases where hidden paralogous sequences have not been separated and where all the individuals present heterozygous sites in the positions where a substitution occurred between the paralogous copies. Five TLR21 genes appear problematic (Pi > 0.01 and Fis < -0.5; Figure S5) and were excluded from further analyses.

The MHC genes are more difficult to analyse. Indeed, heterozygosity could be comparable to divergence under balancing selection. This makes the identification of orthologs very difficult. We identify a variable number of genes among species (from 1 to 10 genes for MHC class I and MHC class II). We checked the sequence similarity for the 10 copies of the MHC class II in *F. albicollis* and the 7 copies of the MHC classI genes in *C. caeruleus* using cd-hit (Fu et al., 2012). For MHC class II, sequence divergences are always higher than 15% indicating that reads will likely be correctly assigned to their corresponding gene copy. For MHC class I, sequence identities could be as high as 95%. In this case, we rely on the fact that the reads from very similar paralogous copies will not be confidently assigned to a gene copy sequence by the mapping software. This will lead to a low mapping score quality and are likely to be discarded

during the genotype calling procedure. For example, 3 out of 7 genes of the *Cyanistes* MHC class I genes could not have been correctly genotyped and are missing from our final dataset.

Data Analysis

SLiM simulations

We use SLiM (vers. 3.3.2; Haller and Messer, 2017) to estimate the impact of demographic changes on polymorphism patterns under various selection regimes. The following parameters were used in all simulations. Sequences of 30kb with a mutation of $4.6e^{-9}$ substitutions/site/generation were simulated (Smeds et al., 2016). Recombination was set to be equal to mutation rate. Introns/exons pattern was reproduced by simulating fragments of 3kb separated by one bp with a very high recombination rate of 0.1 rec./site/generation. Five types of mutations were possible: i) neutral synonymous mutations, ii) non-synonymous mutations with a Distribution of Fitness Effect (DFE) following a gamma law of mean = -0.025 and shape = 0.3, which corresponds to the DFE estimated in Passerines by Rousselle et al. (2020), iii) codominant non-synonymous mutations positively selected with s = 0.1, iv) non-synonymous mutations under balancing selection with an effect on fitness initially set at 0.01 but re-estimated by the program at each generation according to the mutation frequency in the population, thus including a frequency-dependent effect and v) non-synonymous mutations under overdominance using with a dominance coefficient of 1.2.

We simulate a coding sequence organization where positions one and two of the codons were considered as non-degenerated sites, with the non-synonymous types of mutations previously described are possible in various proportions. The third position was considered as completely neutral where only synonymous mutations could appear.

In the absence of control genes evolving under balancing selection, we use SLiM to generate a set of control genes for this category. We simulate two populations of 270,000 and 110,000 individuals, representing mainland and island effective population size respectively.

We also explore the effect of positive and balancing selection on the pattern of Ps and Pn/Ps in a population of size 50,000, 110,000, 270,000 and 500,000. In order to speed up the computational time, we reduce the population size by a factor 100 and rescale mutation rate, recombination rate and selection coefficient accordingly.

All the details of the simulation parameters, calculations of non-synonymous polymorphism rate (Pn) and synonymous polymorphism rate (Ps) of simulated sequences, as well as SLiM command lines are provided in Supplementary Methods and Supplementary Materials.

Polymorphism analyses

Synonymous (Ps) and non-synonymous (Pn) nucleotide diversity were estimated from seq_stat_coding written from the Bio++ library (Available as Supplementary data; Guéguen et al., 2013). The mean Pn/Ps was computed as the sum of Pn over the sum of Ps (Wolf et al., 2009). Ps of concatenated sequences of control genes were estimated for each species of our dataset. For the whole-genome sequence species, we compared the Pn/Ps and Ps estimated obtained using the 97 control genes with the values from Leroy et al., (2021b; ~5000 genes used in their study). Pn/Ps and Ps correlations showed a R^2 of 0.6 and 0.95 respectively (Figure S6). Thus, the 97 control genes used in our study were representative of a larger set. This allowed us to identify *Phylloscopus trochilus* as an outlier. Unlike for all other species (e.g. *Fringilla coelebs*, Figure S7), synonymous polymorphism level was correlated to the amount of missing data in *P. trochilus* alignments (Figure S7). As such, we excluded *P. trochilus* from further analysis.

The mean Pn/Ps, calculated from the concatenated sequences of genes from the same gene class (control genes; BD; TLR; MHC I; MHC II; Database-group; Sma3s-group), was estimated for each bird species. Alternative transcripts were identified based on the genomic position in the GFF file. If several transcripts were available, one transcript was randomly selected. Pn/Ps estimates based on less than four polymorphic sites were excluded from the analysis, as were those with no polymorphic non-synonymous sites.

Statistical analyses

To estimate the impact of demographic history on genome-wide polymorphism of island species and the potentially reduced constraints on their immune genes, we computed the ratio of non-synonymous nucleotide diversity over synonymous nucleotide diversity (Pn/Ps). A linear mixed model was performed, using the Pn/Ps ratio as dependent variable and, as explanatory variables, the mainland or insular origin of species as well as the category of genes (packages lme4 and lmerTest (Bates et al., 2012; Kuznetsova et al., 2017)). In order to take the phylogenetic effect into account, the taxonomic rank “family” was included as a random effect in the model. We also used a generalized linear mixed model (using the function glmer of the

package lme4) with the family "Gamma(link="log")" which leads to the same results (Figure S15 to S24). Five linear mixed models were defined i) null model, ii) model with only the origin parameter, iii) model with only the gene category parameter, iv) model using both origin and gene category parameters, and finally v) model including those two parameters and the interaction effect. In some cases, the phylogenetic effect was difficult to estimate because the number of species per family was reduced to one. In that case, we chose to reduce the number of families by grouping Turdidae with Muscicapidae, Nectariniidae, and Estrildidae with Ploceidae and Fringillidae within Thraupidae. The results obtained with these family groupings were similar to the original model (Table S1), except when stated. The categories Database-group and Sma3s-group were tested separately from the Core group because they contained hundreds of genes annotated using the automatic pipeline that were only available for species with genome wide data. Database-group and Sma3s-group were not analysed simultaneously because they contained a partially overlapping set of genes. Finally, genes evolving under purifying selection and genes evolving under balancing selection were also analysed separately. Model selection was based on two methods. First, we use the difference in corrected Akaike Information Criterion (ΔAICc) calculated using the qpcR package (Spiess and Spiess, 2018). Second, a model simplification using an ANOVA between models was also performed.

We also tested an alternative model using the difference between Pn/Ps of immune genes and control genes (*Δ*Pn/Ps) as dependent variable, and species origin as explanatory variable. Under the hypothesis of a relaxation in selection pressure on islands due to a change in the parasite community, we expect the *Δ*Pn/Ps to be higher on island species compared to the mainland ones and, therefore, the species origin (i.e., mainland or island) to be significant. In this model, we used the Phylogenetic Generalized Least Squares model (PGLS; implemented in the "nlme" packages; Pinheiro et al., 2017). This model assumes that the covariance between species follows a Brownian motion evolution process along the phylogeny (implemented using the "corBrownian" function from the '"ape"' package; Paradis and Schliep, 2019). The species phylogeny was estimated using mitochondrial genes and a maximum likelihood inference implemented in IQTREE (model GTR+Gamma and ultrafast bootstrap; Nguyen et al., 2014; median of 11,134 bp analysed per species). The phylogeny with the bootstrap support is provided as supplementary material.

All the statistical analyses were performed using R (R Core Team, 2018), and dplyr package (Wickham, 2016). Graphical representations were done using ggplot2, ggrepel, ggpubr and ggpmisc (Aphalo, 2020; Kassambara, 2018; Slowikowski et al., 2018; Wickham, 2016).

Results

For the 150 individuals (10 species with 15 individuals each) for which we generated new data by targeted capture sequencing, an average of 3.3 million paired-ends reads per individual was generated (Table S1). After mapping, genotyping and cleaning, we analysed 86 control and 16 immune genes on average per species, out of the 141 targeted genes (120 control and 21 immune related genes; Table S4). For the species with whole-genome sequences, we analysed 106 control and 20 immune genes on average per species, out of the 141 targeted genes, and 875 and 688 genes on average in the Database-group and Sma3s-group respectively (Table S4).

For the species for which full genome sequences were available, the Ps and Pn/Ps estimated using the control genes reflect the Ps and Pn/Ps of the whole transcriptome (Figure S6).

Population genetics of BD and TLR Immune genes

In order to characterize the selection regimes shaping the BD and TLR polymorphisms, we first analyze the variation of Pn/Ps ratios among gene categories using a linear mixed model.

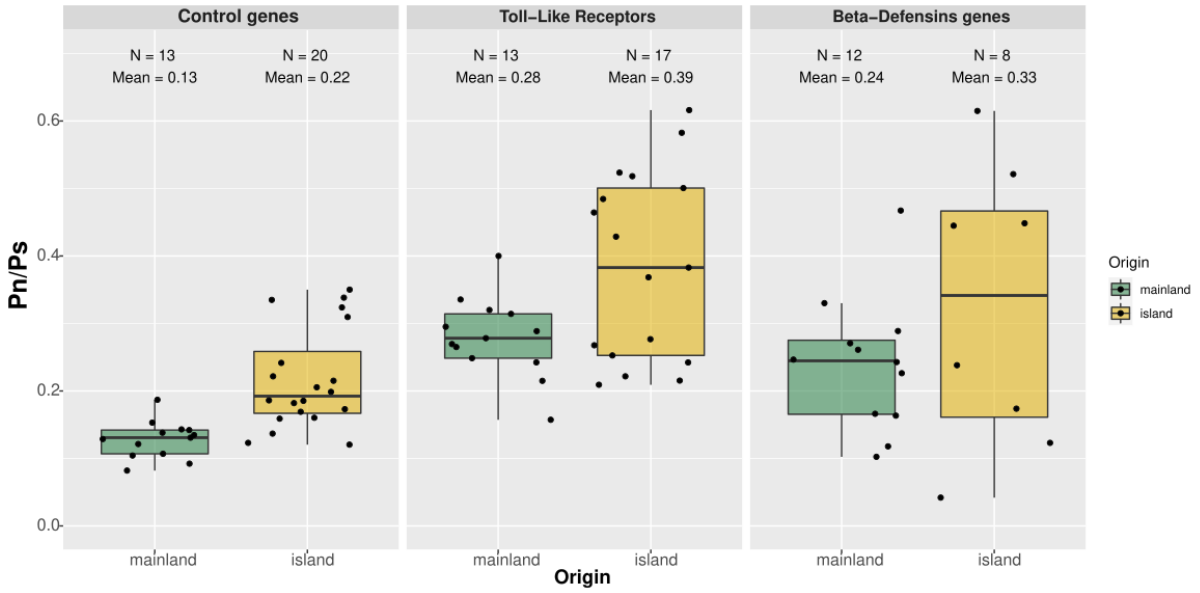

Figure 3: Pn/Ps according to species origin (mainland in green and insular in orange) for different gene categories under purifying selection. The number of species (N), and the mean Pn/Ps are shown for each modality.

Model selection based on AICc as well as model selection approach based on simplification with ANOVA identified the model including the origin (i.e., mainland or island) and gene category without interaction (Table 2). In this model, island origin of species is associated with a greater Pn/Ps (0.14 vs. 0.10; Table 3; $p < 0.01$). Gene categories corresponding to TLRs and BDs showed a significantly higher Pn/Ps than control genes (Table 3; $p < 0.001$). Our statistical analysis confirms that island birds have a higher Pn/Ps ratio than mainland relatives, in agreement with the nearly-neutral theory of evolution. It also reveals that immune genes have a higher Pn/Ps than randomly selected control genes suggesting that BD and TLR evolve under a different selection regime than non-immune related genes.

Next, we investigate the cause of the higher Pn/Ps of immune genes by testing three hypotheses. First, we exclude a bias due to a lower number of genes in immune genes, and therefore higher variance in the estimation of Pn/Ps~~,~~ in immune genes. Immune genes still have significantly higher Pn/Ps compared to a random subsample of control genes of comparable size (Figure S8 & S9). Second, the Pn/Ps of immune genes could be inflated by positive selection. It is well known that immune genes are subject to frequent adaptation due to harm race evolution with pathogens (Enard et al., 2016; Shultz and Sackton, 2019; Velová et al., 2018). We evaluate the effect of positively selected genes on the Pn/Ps using SLiM simulations with both positively and negatively selected mutations. The presence of recurrent positive selection could increase the Pn/Ps leading to a higher Pn/Ps in immune genes if this category is more prone to adaptive evolution (Figure 4A). However, positive selection always leads to a drastic decrease in Ps due to genetic sweep effect at linked sites (Figure 4B). BDs and TLRs have a slightly higher or similar Ps than control genes (Figure S9, mean Ps = 0.007, 0.004 and 0.003 for BDs, TLRs and control genes respectively, effect of gene category $p < 0.1$) and, as a consequence, even if positive selection is likely to have impacted the evolution of immune genes, it is not the cause of the higher Pn/Ps observed here. Third, balancing selection could be present, at least temporarily, in the evolution of BDs and TLRs genes (Kloch et al., 2018; Levy et al., 2020). Simulation analyses confirm that balancing selection causes an increase of Ps and Pn/Ps (Figure 4C & 4D). However, a change in effective population size has an opposite effect on the Pn/Ps according to the type of selection. In the presence of slightly deleterious mutations, Pn/Ps decreases with *Ne* whereas it increases in the presence of balancing selection. Island birds have higher Pn/Ps ratios than mainland birds for BDs and TLRs. Therefore, we can rule out balancing selection as the main factor explaining the high Pn/Ps of immune genes because, in this case, Pn/Ps of island birds should be lower. The last possible explanation we can think of

is a relaxed selection of immune genes. It is likely that immune genes are overall less constrained than the control genes. It has been shown that evolutionary constraints are more related to gene expression than to function (Drummond et al., 2005; Drummond and Wilke, 2008) and therefore, functionally important genes could still have a high Pn/Ps.

Overall, our analyses do not support a strong impact of ongoing adaptive mutation or balancing selection on BDs and TLRs. However, these immune genes do not evolve as the random genes not involved in immune functions and present a significantly higher Pn/Ps of 0.20 ($p < 0.001$; Table 3).

No evidence of a reduced impact of the parasite communities on the polymorphism pattern immunes genes in island birds

For BDs and TLRs, the best model selected includes the origin (i.e., mainland or island) and gene category without interaction (see above and Table 2). This model has no interaction between origin and gene categories invalidating the hypothesis of a reduced parasite communities on island (Figure 2).

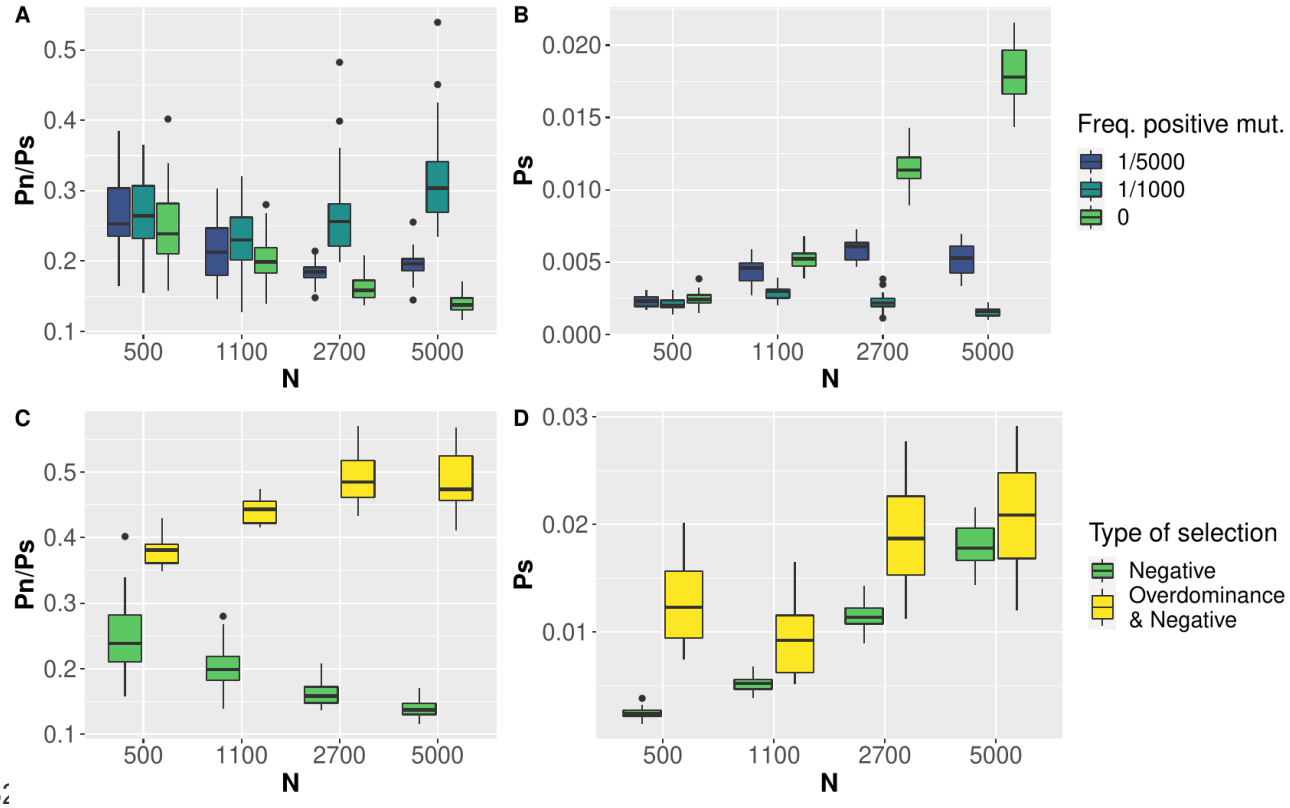

Figure 4: Neutral polymorphism (Ps) and ratio of selected over neutral polymorphism (Pn/Ps) estimated from SLiM simulations. A) Pn/Ps as a function of population size, N and B) Ps as a

function of N. In both A and B, colour indicates the frequency of positively selected mutation compare to deleterious mutation. C) Pn/Ps as a function of N and D) Ps as a function of N. In both C and D, yellow indicates simulations with overdominance mutation (h = 1.2) and negatively selected mutations and green indicates simulations with only negatively selected mutations.

Table 2: Statistical model explaining Pn/Ps variation of Toll-Like Receptors, Beta-Defensins genes, and control genes. The p-values of ANOVA test between simpler models are not reported if a more complex model explains a larger proportion of the variance.

For larger sets of genes, identified using an automatic pipeline and gene annotation, model selection based on AICc and simplification with ANOVA (Table S5, S8) identified models that included origine parameters which associated a higher Pn/Ps of at least 0.07 for island species (p < 0.001; Table S6, S7, S9, S10, Figure 5). Selection model by simplification with

ANOVA identified models with interaction effect between origin and gene category associated with a reduced Pn/Ps for immune genes of island species that invalidate our hypothesis (Table S7, S10).

The alternative statistical approach using the difference between Pn/Ps of immune genes and control genes (*Δ*Pn/Ps) as dependent variable, and species origin as explanatory variable under a PGLS framework lead to similar results. Island was never associated to a statistically higher *Δ*Pn/Ps (table S2) providing no support for an increased relaxed selection of immune genes in island species.

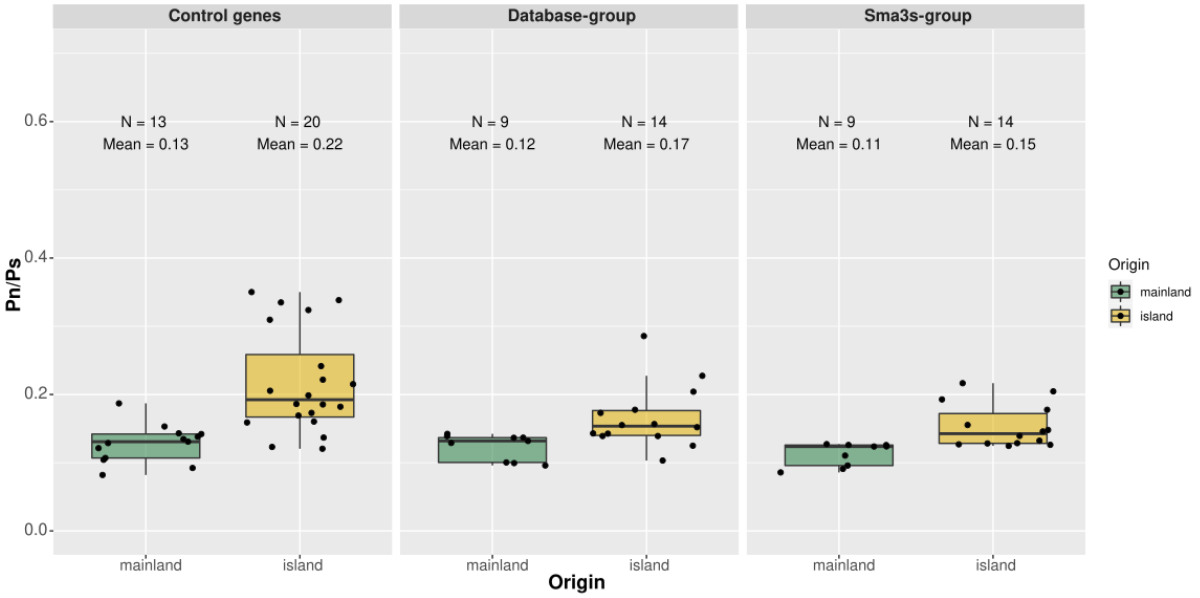

Figure 5: Boxplot of Pn/Ps according to species origin (mainland in green and insular in orange) for different gene categories under purifying selection. The number of individuals (N), and the mean Pn/Ps are shown for each modality.

Genes under balancing selection

First, we estimated the effect of population size variation on the Pn/Ps of the genes evolving under balancing selection by simulating sequences under frequency dependent or overdominance selection using SLiM (see Methods and Supplementary Methods). The simulation under frequency dependence selection revealed an average Pn/Ps equal to 0.8 for island species and 1.2 for mainland species (Figure 6). Under overdominance, simulated sequences from island and mainland populations respectively have an average Pn/Ps equal to 0.54 and 1.03 (Figure 6).

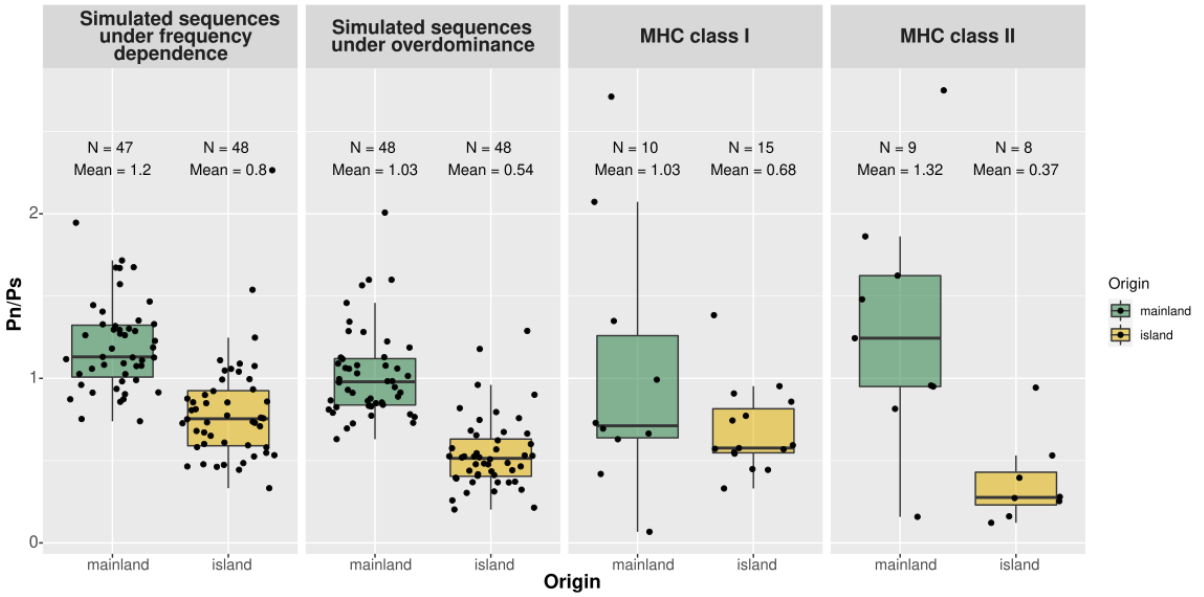

Figure 6: Boxplot of Pn/Ps according to species origin (mainland in green and insular in orange) for different gene categories under balancing selection. The number of species (N), and the mean Pn/Ps are shown for each modality. The control groups correspond to the results obtained from simulated sequence via SLiM (see Methods and Supplementary Methods Simulation of control genes under balancing selection).

Using simulations under frequency dependence selection as well as simulations under the overdominance, model selection by AIC identifies the model with origin as the best, contrary to the method by simplification with ANOVA which identified the full model therefore including significant interaction between origin and genes category (Table 4). This interaction effect is significant for the MHC II ($p < 0.05$, Table S12) but not for MHC I. As expected, island species have a significantly lower Pn/Ps in MHC genes compared to mainland species ($p < 0.01$; except for the full model based on control genes evolving under overdominance Table S12).

Table 4: Statistical model explaining Pn/Ps variation of genes under balancing selection (i.e MHC class I and II), and simulated sequences under i) frequency dependence or ii) overdominance. The p-values of ANOVA test between simpler models are not reported if a more complex model explains a larger proportion of the variance.

Discussion

On oceanic islands, the depauperate parasite community is expected to lead to a relaxation of selection on the immune system. In this study, we found support for such an effect, but only on MHC class II genes and using simulated sequences under balancing selection as control. No effect was detected for MHC class I genes nor for innate immune genes (TLRs and BDs), evolving under purifying selection. On these gene sets, increased drift effects on island populations limit the efficacy of selection in accordance with the nearly-neutral theory (Ohta, 1992). The ability to distinguish between the selective and nearly-neutral processes (relaxed selection due to environmental change vs. drift) could only be achieved by our approach of using random genes (i.e., “control genes") to estimate the genome-wide effect of potential variation in effective population size between populations.

Effects of effective population size variation

Our results support the nearly-neutral theory of evolution for those genes under purifying selection, whereby strong genetic drift acting on small island populations reduces the efficacy of natural selection, leading to an increase in non-synonymous nucleotide diversity compared to the mostly neutral, synonymous nucleotide diversity (i.e., Pn/Ps; Ohta, 1992). This is materialized by a genome-wide increase in frequency of weakly deleterious mutations (Kutschera et al., 2020; Leroy et al., 2021b; Loire et al., 2013; Robinson et al., 2016; Rogers and Slatkin, 2017).

For genes evolving under balancing selection, we performed simulations under the hypotheses of overdominance (heterozygote advantage) or frequency dependence (rare-allele advantage). Our results showed reduced Pn/Ps for smaller population sizes (Figure 6, S10, S11). This simulation confirmed our expectations (Figure 2) that a reduction in the efficacy of selection results in a decrease in the frequency of non-synonymous polymorphism, as, under normal circumstances, selection maintains those mutations at intermediate frequencies. It also matches what we obtained in the empirical results, where both MHC classes I and II had a reduced Pn/Ps in island birds. This result supports that the fitness effect of having non-synonymous polymorphisms segregating at high frequencies is not strong enough to counteract entirely the effect of genetic drift on islands, therefore extending the nearly-neutral theory to the overdominance type of selection.

Effects of selection on immune genes

For immune genes, we try to characterize the nature of the selection acting on BDs and TLRs genes. Comparing those genes with control genes and using simulations, we were able to rule out that directional positive selection and balancing selection had a major impact shaping the polymorphism of these immune genes. In contrast, the pattern of Pn/Ps between island and mainland populations is in line with the effect of purifying selection in the presence of slightly deleterious mutation. However, no effect was detected on insular species, beyond what could be attributed to genetic drift. This is in line with the result of Gonzalez-Quevedo et al. (2015b) and Grueber et al. (2013) who found that TLR genetic diversity was mostly influenced by genetic drift. At first sight, this result seems not in line with the fact that island parasite communities are less diverse (Beadell et al., 2006; Loiseau et al., 2017; Maria et al., 2009; Pérez-Rodríguez et al., 2013; but see Illera et al., 2015). However, a reduced pathogens number has also been found to be associated with a higher prevalence in birds and reptiles from the

Macaronesian archipelago (Illera and Perera, 2020). Therefore, these two patterns, i.e. a less diverse pathogen's community on islands with a higher prevalence, could still imply a strong selection pressure on immune genes.

In contrast, for MHC genes that unambiguously evolve under balancing selection, MHC class II genes presented a reduction in non-synonymous polymorphism larger than the effects of drift alone, when simulated sequences are used as control. This was the only case where a role for relaxed selection pressures in the molecular evolution of immune genes could be invoked.

Our results are in accordance with the hypothesis of Lee (2006), which proposes that innate and acquired immunity may exhibit distinct responses to changes in pressures due to different costs and benefits. However, our result contrasts with the study of Santonastaso et al. (2017) that identified no change in selection pressures on MHC II genes in a lizard species, concluding that their evolution was mostly governed by drift. Similarly, Agudo et al. (2011) also found a prominent role for genetic drift over selection in the evolution of MHC II genes in the Egyption vulture (*Neophron percnopterus*).

Our results rely on simulations that may be affected by the choice of the parameter values. First, we performed simulations using a fixed effective population size (*Ne*) estimated from the polymorphism data. Using others values of *Ne* had a weak impact on the relative difference between island and mainland species for the overdominance type of selection (Figure S10, S11). Secondly, we simulated two types of selection, namely overdominance (Doherty and Zinkernagel, 1975) and frequency dependence (Slade and McCallum, 1992), but it has been argued that the maintenance of MHC polymorphism could be the result of fluctuating selection (Hill, 1991). Additionally, recombination and gene conversion has also been put forward as a mechanism responsible for generating diversity (Spurgin et al., 2011). Therefore, our results for the MHC II, which is based on the relative difference between Pn/Ps of island and mainland species comparing empirical and simulated data, should be taken cautiously as their significance can be dependent on the specific parameters that we used, although we did our best to select a realistic range of parameters.

The observed difference between MHC class I and II could be explained by their different pathogen targets: MHC class I genes are primarily involved in the recognition of intracellular pathogens (Kappes and Strominger, 1988), while MHC class II genes are directly involved in the recognition of extracellular pathogens (Bjorkman and Parham, 1990). These differences

589 could lead to variable selection pressures depending on the extracellular versus intracellular
590 parasite communities present on islands. In addition, the relaxed selection pressures on MHC
591 II genes from adaptive immunity is in line with a reduction in acquired immunity parameters
592 observed by Lobato et al. (2017) that used partly the same sets of species.

593 As a perspective of our work, we should mention that there is an extensive variation in the
594 number of MHC gene copies across the avian phylogeny (Minias et al., 2019; O'Connor et al.,
595 2020). Particularly, it was recently discovered that Passerines have a very dynamic evolution
596 of duplication/loss events compared to other birds (Minias et al., 2019). Here, we used the two
597 copies of MHC gene I and II currently annotated in the collared flycatcher genome as target
598 sequences for our targeted-capture sequencing. The future improvement of genome assembly,
599 thanks to the development of long-reads technology (Peona et al., 2021, 2018), will certainly
600 help to precisely annotate all MHC copies and to study the whole repertoire of MHC genes.

601 *Consequences of drift ~~effect~~ and selection on immunity*

602 The potential relaxation of the natural selection acting on immune genes in island species is
603 expected to reduce immune functions and increase susceptibility of island populations to
604 pathogens. This is true even if this relaxation is only the consequence of a reduction in the
605 effective population size and not caused by a reduction of the pressure exerted by the parasitic
606 community. This is in line with the results of Hawley et al. (2005) and Belasen et al. (2019)
607 who showed that a decrease in diversity of immune loci (MHC II or through immune proxy)
608 was associated with a reduction in immune functions. It should be noted that even if migration
609 rate is reduced on islands, sedentary and endemic island species are not completely free from
610 the exposure of exogen pathogens through migratory birds (Levin et al., 2013).

611 As a final remark, we would like to stress that more research is still needed (i) to ascertain both
612 selection pressures on innate and adaptive immune responses and the load of deleterious
613 mutations due to drift, also identified by an increasing body of work (Loire et al., 2013;
614 Robinson et al., 2016; Rogers and Slatkin, 2017; Kutschera et al., 2020; Leroy et al., 2021b),
615 and (ii) to describe island parasite communities. To date, most of the studies investigated
616 intracellular parasite communities on islands, and more specifically haemosporidian parasites,
617 avian pox and coccidian parasites (Cornuault et al., 2012; Illera et al., 2015, 2008; Ishtiaq et
618 al., 2010; Loiseau et al., 2017; Martinez et al., 2015; Padilla et al., 2017; Pérez-Rodríguez et
619 al., 2013; Silva-Iturriza et al., 2012), whereas very few evaluated the extracellular parasite

diversity, such as helminths (Nieberding et al., 2006) but see the review of Illera and Perera (2020) for reptiles. Metabarcoding of parasites is a new technique to evaluate at the same time both communities of intracellular and extracellular parasites (Bourret et al., 2021) and might therefore be a promising approach to evaluate their communities in island and mainland populations.

Conclusion

Our comparative population genomics study has investigated the combined effects of drift and selection on immune genes from island and mainland passerines. The study of synonymous and non-synonymous polymorphism of these genes confirmed that island species, with smaller population sizes than their mainland counterparts, were more impacted by drift, which induces a load of weakly deleterious mutations in their genome. Indeed most of the genes studied here involved in the immune response do not show a statistically different pattern from control genes. Only MHC II genes, involved in the recognition of extracellular pathogens, showed a reduction in their non-synonymous polymorphism in island species. This response, which may be attributed to reduced selection pressures on these genes, could be associated with the suspected reduced parasitic communities on islands. The increased load of deleterious mutations as well as the potential relaxed selection pressures on MHC II support the reduced immune functions of island species, which could be added to the list of other convergent responses of the island syndrome.

Data availability

Datasets, scripts, supplementary figures and texts are available on figshare : https://figshare.com/s/ab7004cc2f4415b4058f. The reads newly generated for this study have been deposited in the NCBI Sequence Read Archive under the bioproject PRJNA724656.

Acknowledgments

In Gabon, we thank the Director and the guides of the Lekedi Park, Marie Charpentier for her help in organizing the expedition, and Alexandre Vaz for field assistance and outreach work. In São Tomé and Príncipe, we thank the Directorate of the Environment and the Department for Nature Conservation, its directors—Arlindo Carvalho and Victor Bonfim—Guilhermino, the Association Monte Pico, its president Luis Mário, and its members. Philippe Perret, Octávio Veiga, Bikegila, and Yelli provided invaluable assistance in the field. Permissions for fieldwork were given by the authorities of São Tomé and Príncipe and Gabon (CENAREST

authorization No. AR0053/12/MENESTFPRSCJS/ CENAREST/CG/CST/CSAR). Permits for the Canary Islands were provided by the Regional Government (Ref.: 2012/0710), and the Cabildo of La Palma and Tenerife. In Montpellier, we thank the blue tit team (https://oreme.org/observation/ecopop/mesanges/) for the capture of the individuals used in this study. The analyses benefited from the Montpellier Bioinformatics Biodiversity (MBB) platform services. This research was conducted in the scope of the international twin-lab "LIA – Biodiversity and Evolution" between CIBIO (Portugal) and ISEM and CEFE-CNRS (France).

Funding information

This research was funded by the Labex CeMEB (project ISLAND IMMUNITY) for BN, the ANR (BirdIslandGenomic project, ANR-14-CE02-0002) for MB, BN, CL and CD, the National Geographic Society (Grant/Award Number:W251-12), the British Ecological Society (Grant/Award Number: 369/4558), the portuguese Foundation for Science and Technology under the PTDC/BIA-EVL/29390/2017 "DEEP" Research Project for MM, RC and CL and the Spanish Ministry of Science, Innovation and Universities, and the European Regional Development Fund (Ref.: PGC2018-097575-B-I00) for JCI.
