Abstract

Symbiosis is a continuum of long-term interactions ranging from mutualism to parasitism, according to the balance between costs and benefits for the protagonists. The density of endosymbiont is, in both cases, a key factor that determines both the transmission of symbiota and the host extended phenotype, and is thus tightly regulated within hosts. However, the evolutionary and molecular mechanisms underlying bacterial density regulation are currently poorly understood. In this context, the symbiosis between the fruit fly and its intracellular bacteria Wolbachia (wMelPop strain) is particularly interesting to study. Although vertically transmitted, the symbiont is pathogenic, and a positive correlation between virulence and pathogenic, and the bacterial density is observed. In addition, the number of repeats of a bacterial genomic region -Octomom- is positively correlated with Wolbachia density, underlying a potential genetic mechanism that controls bacterial density. Interestingly, the number of repeats varies between host individuals, but most likely also within them. Such genetic heterogeneity within the host could promote conflicts between bacteria themselves and with the host, notably by increasing within-host competition between symbiont genotypes through a process analogous to the tragedy of the commons. To characterize the determinisms at play in the regulation of bacterial density, we first introgressed wMelPop in different genetic backgrounds of D. melanogaster, and found different density levels and Octomom copy numbers in each host lineage. To determine whether such variations reflect a host genetic determination on density regulation through Octomom copy number selection, we replicated the introgressions and performed reciprocal crosses on the two Drosophila populations with the most extreme density levels. In both experiments, we detected an absence of directionality in the patterns of infection, associated with a strong instability of these patterns across generations. Given that bacterial density was highly correlated with Octomom copy numbers in all experiments, these results rather suggest a strong influence of drift and a random increase in the frequency of certain bacterial variants. We then discuss how drift, both on the symbiont population during transmission and on the host population, could limit the efficiency of selection in such a symbiotic system, and the consequences of drift on the regulation of density and composition of bacterial populations.

Keywords: Symbiosis, Wolbachia, Drosophila, density regulation, drift
**Introduction**

A majority of organisms live in symbiosis, a close relationship between two organisms belonging to different species that ranges along the continuum between parasitism and mutualism [De Bary, 1879; Tipton, Darcy and Hynson, 2019]. In the case of microorganisms, the regulation of the symbiont population within the host, and particularly their abundance within host tissues, are important characteristics that shape the tight relationship between partners and influence the position of the symbiosis along the mutualism-parasitism continuum [Tivel, 1991; Douglas, 1994]. Research on disease evolution has further shown that the evolution of virulence is balanced by the transmission of symbionts to new hosts, and that both virulence and transmission rely on the regulation of the symbiotic density [Anderson and May, 1982]. On the one side, an increased virulence can benefit symbionts by increasing their instantaneous transmission, as they exploit more host resources and thus increase their replication within the host. On the other side, the more abundant the symbionts are in host tissues, the more they cost to the host, which shortens the host life span and thereby the window of transmission of the symbiont. As a result, the virulence/transmission trade-off leads to an optimum that optimizes symbiont transmission over the entire life of the host. More specifically in vertically transmitted symbioses, the optimum symbiotic density optimizes both the production of offspring and their colonization by symbionts.

Symbiont density is thus under strong regulation [O’Neill, Hoffmann and Werren, 1997; Alizon et al., 2009], and many factors can contribute to its control (López-Madrigal and Duarte, 2019). In insects for instance, host factors can play a major role in regulating the symbiont population [Poinot et al., 1998; Douglas, 2014] through the activation of immune pathways, such as DUOX or Toll [Douglas, Bouvaine and Russell, 2011; You, Lee and Lee, 2009]. Symbionts can also be involved in their own regulation according to particular genetic factors [Jichi et al., 2002; Chrostek et al., 2013]. This is for example the case in symbioses between wasps and vertically transmitted bacteria, where densities of Wolbachia are strain-specific in co-infection [Mouton et al., 2003, 2004]. Still, some mechanisms involved in bacterial regulation are poorly understood in insects. For instance, the target of bacterial regulation remains to be clarified: does the host control the overall symbiont population by decreasing symbiont abundance regardless the symbiont genetic specificity or does it target specific variants? Also, control mechanisms that are independent of classical immune pathways are worth exploring. For instance, are cases where hosts sanction symbiont through differential allocation of metabolites frequent and widespread in symbiotic associations (Douglas, 2008)?

There is much evidence to suggest that selection should lead to symbiotic population control systems (Douglas, 2014), but two evolutionary mechanisms could limit the effectiveness of selection on density regulation and should also be considered: conflicts between different levels of selection and drift. In terms of selection levels, between-host selection predicts that any excessive replication would be detrimental to host fitness, thus selecting for symbiotic variants that are the least harmful while being well transmitted [Sathmáry and Smith, 1995]. On the contrary, the competition that occurs within the host tissues should favor symbiont variants that are the most efficient to rapidly colonize the host, thus those that have the most proliferative abilities regardless of the cost paid by the host [Alizon, de Roode and Michalakis, 2013]. This raises the question of whether within- and between-host
selection create an evolutionary conflict regarding the control of symbiont density, by favoring symbiont strains with opposite replication profiles (O’Neill, Hoffmann and Werren, 1997; Monnin et al., 2020). Finally, the importance of drift in vertically transmitted symbioses could be more considered. Indeed, bottlenecks during transmission reduce the genetic diversity in the following host generation and may limit the effectiveness of selection upon symbiotic population regulation (Mathé-Hubert et al., 2019). Such molecular and evolutionary mechanisms poorly studied, especially in vertically transmitted symbioses, although they can play an important role in the epidemiological and evolutionary dynamics of symbiotic interactions. A first limitation is conceptual, as populations of vertically transmitted endosymbionts tend to be considered with little or no heterogeneity, thus limiting the potential for within-host selection. However, while recurrent bottlenecks during transmission tend to reduce diversity, heterogeneity can still be observed in certain systems (Banks and Birky, 1985; Birky, Fuerst and Maruyama, 1989; Abbot and Moran, 2002; Asnicar et al., 2017). A second –more practical– limitation is that if heterogeneity does exist in symbiont populations, it is difficult to trace it experimentally, because of the absence of genetic markers.

A good study model to address questions related to density control is the maternally transmitted bacterium Wolbachia in association with Drosophila melanogaster hosts. In particular, the virulent wMelPop strain (Min and Benzer, 1997), which can exhibit heterogeneous density levels between individuals, has differential virulence profiles. Virulence is notably correlated to a tandem amplification of the genomic region “Octomom” (Chrostek et al., 2013). Indeed, flies harboring Wolbachia with more copies of Octomom exhibit high density levels in their tissues and a reduced lifespan, while those harboring Wolbachia with fewer copies exhibit low density levels and survive longer (Chrostek and Teixeira, 2015). This model system is therefore advantageous because hosts and symbionts can exhibit genetic variability, and because the number of Octomom copies can be used as a marker to track the evolution of the symbiotic population. Moreover, previous studies showed that within-host selection can occur in the wMelPop strain of D. melanogaster (Chrostek & Teixeira, 2016; Monnin et al., 2020).

In this study, we take advantage of this Drosophila-wMelPop symbiosis to shed light on the evolutionary determinisms that act on the regulation of vertically transmitted symbionts in insects. We investigate whether the host genetic background can directly influence the density of the symbionts, or whether the symbionts self-regulate their density via Octomom. Using different host genetic backgrounds and a combination of introgressions and crossing experiments, we analyze the respective role of host and symbiont backgrounds, but also drift, in the evolution of density and genetic composition of the symbiotic population.
Materials and Methods

Model system

*Drosophila melanogaster* flies were trapped in different locations (Arabia, Bolivia, China (Canton), Republic of the Congo - RC (Brazzaville), USA (Seattle) (Viera et al., 1999) and France (Sainte-Foy-lès-Lyon)). These populations have been maintained in the laboratory by regular sib mating for at least 10 years and are considered as genetically homogeneous. In the following experiments, we used these 6 inbred lines (*Wolbachia*-free) plus the w1118 line, infected either by the Wolbachia strain wMePop (provided by Scott O’Neill (Monash University, Australia)) or by the strain wMeCS (provided by J. Martinez/F. Jiggins, Cambridge University, UK).

Rearing and collection

Flies were maintained under 12-hour day/night cycles at constant temperature and hygrometry (25°C and 60% relative humidity) and reared on rich medium (for 1 L of medium: 73.3 g of Gaude flour, 76.7 g of inactive brewer’s yeast, 8.89 g of agar-agar powder, 4 g of Tegosept - Nipagine, 0.4 L of distilled water and 55.5 mL of 93% ethanol).

With the exception of introgression experiments (see below), each new generation was established by tube transfer of approximately 80 randomly selected 4/5-day old individuals, to ensure full fertility of the flies. To control larval competition prior to sampling for infection patterns, we pooled about 80 flies in egg-laying cages and transferred 100 eggs laid by 4/5-day old females onto a rich medium pellet (1 mL) placed in a tube of agarose medium. After hatching, flies were transferred to an agarose medium supplemented with sugar (10%) and were collected after 7 days to be frozen and stored at -20°C.

Wolbachia introgression within various host genetic backgrounds

The symbiotic introgression method allows to transmit symbionts from a donor line to a recipient line while conserving most of the genetic background of the recipient line. *As Wolbachia is a maternally transmitted bacterial symbiont*, this method consists here in making a first cross between *Wolbachia*-infected females (here, n = 20) from the donor line with *Wolbachia*-uninfected males (here, n = 10) from the recipient line. Then, the F1 progeny of this previous cross carries the Wolbachia symbionts from the donor line and shares half of its genetic background between the donor and the recipient lines. Two additional backcrosses between females (n = 20) from the F1 (and then F2) progeny and males (n = 10) from the recipient lines are necessary to restore at the F3 generation 87.5% of the genetic background of the recipient line (Figure 1).

Figure 1: Introgession and reciprocal crosses procedures.

Transmission of symbionts from females of the donor line (red or blue) to a recipient line (green or orange). Serial backcrosses were performed to restore the recipient host genetic background by mating daughters from the previous cross with males from the recipient line. This method was applied to infect the 6 natural *Drosophila melanogaster* populations by wMelpop (experiment #1, left panel), to perform new introgressions from Bolivia or USA on 3 replicates (experiment #2, left panel) and to conduct reciprocal crosses (experiment #3, right panel).
We first applied this method to infect the 6 natural Drosophila melanogaster population lines with the wMelPop-strain (experiment #1, MP1 lines). For this purpose, we used an iso-female w1118 line infected by wMelPop (IsoA3) as the donor line and the other populations as recipient lines (1 introgression / line). After two generations of regular sib-mating, flies were placed in egg-laying cages for sampling (see ‘rearing and collection’ protocol above), and infection patterns (i.e., wMelPop relative density and the average Octomom copy number per bacteria in flies) were checked by qPCR in these lines.

As the introgression of wMelPop in different recipient lines (experiment #1) resulted in different infection patterns (i.e., density and number of Octomom copies), we tested 8 generations later (experiment #2) the replicability of the infection pattern after a new introgression procedure. For this purpose, we selected two recipient lines (USA and Bolivia) that exhibited extreme infection patterns after introgression (i.e., USA-MP1 exhibited a high wMelPop density whereas Bolivia-MP1 exhibited a low wMelPop density, see results), and performed a new 3 independent symbiotic introgressions, using the same iso-female line (IsoA3, 12 generations after the first introgression procedure) as the donor line and these two populations (USA and Bolivia) as recipient lines. After 3 generations of backcrosses, Bolivia-MP2 and USA-MP2 flies were maintained under regular sib-mating (except the generation preceding each sampling, for which the larval density was controlled).

In parallel to experiment #2, we independently performed reciprocal crosses between the Bolivia-MP1 and USA-MP1 lines (i.e., lines infected by wMelPop during the first introgression experiment) to test the respective influence of host and symbiotic genetic backgrounds on the wMelPop proliferation within flies. For this purpose, we reciprocally backcrossed Bolivia-MP1 and USA-MP1 individuals for 3 generations (experiment #3), 3 independent replicates). After 3 backcrosses, flies were maintained under regular sib-mating (except the generation preceding each sampling, in which the larval density was controlled).

Quantification of wMelPop density and Octomom copy number

Wolbachia density and Octomom copy number were measured on 7-day-old females (n = 5 flies / line / timepoint experiments #2 and #3), whose DNA was extracted using the EZ-10 96-well Plate Animal Genomic DNA® kit (Bio Basic). In brief, flies were individually crushed in 400 µL of lysis buffer by a sterile 5-mm stainless bead shaken by a TissueLyser® (Qiagen) for 30 s at 25 Hz. DNA was extracted following the instructions from the manufacturer, eluted in 100 µL of elution buffer and stored at -20°C.

Relative Wolbachia density and Octomom copy number were quantified from the same DNA extract by quantitative real-time PCR using SYBR® green and following the MIQE guideline applied to DNA samples (Bustin et al., 2009). To quantify the average amount of wMelPop per fly, we used primers targeting a monocopy reference gene in the host (RP49 in Drosophila melanogaster) and primers targeting a monocopy gene outside of the Octomom region in Wolbachia (WD0505 in wMelPop). Then, we normalized the number of copies of WD0505 by the number of copies of the reference gene RP49 to estimate the relative density of wMelPop per fly (Monnin et al., 2020). To quantify the average Octomom copy number of the wMelPop population within a fly, we used primers targeting the same gene located outside the Octomom copy number in the wMelPop genome (WD0505) and primers targeting a gene inside the Octomom region (WD0513). Then, we normalized the number of copies of WD0513 by the number of
copies of WD0505 to estimate the mean Octomom copy number of the wMeiPop population per fly (Chróstek et al., 2013). The sequences of the primers used (synthesis by Eurogentec) are available in the Table S1.

The PCR amplifications were performed on a CFX96 instrument (Bio-Rad), independently for each target gene. Four µL of a diluted DNA sample (1/25), 0.5 µL of each forward and reverse primer (10 µM) and 5 µL of SsoADV Universal SYBR® Green Supermix (Bio-Rad) were used, for a total volume of 10 µL. The reaction conditions for amplification were 95 °C for 3 min of preincubation, followed by 40 cycles of (95 °C for 10 s for denaturation, 60 °C for 10 s for hybridization and 68 °C for 15 s for elongation). The mean primer efficiencies were calculated using 6 points (in duplicate) from a 10-fold dilution series (10² to 10⁴ copies) of previously purified PCR products (Table S1).

The cycle quantification (Cq) values were estimated by the regression method, and the mean Cq value between technical duplicates was used for the determination of individual DNA quantities (deviation between duplicates below 0.5 cycles).

**Statistical analyses**

We used the R software (version 4.0.3) for all analyses (R Core Team, 2020). Density and Octomom copy number ratios were estimated and normalized from the Cq values using the EasyqpcR package (Le Pape, 2012), based on the qBase algorithms published by Hellemans et al. (2007), taking into account the efficiency of primers. We first used a control sample from an aliquoted DNA extract (w1118 line infected by the Wolbachia wMeiCS strain) as a calibrator, to estimate the inter-plate variability. We took this variability into account to normalize data between plates using the EasyqpcR package, and determined the quantity of WD0505 relative to RP49 and of WD0513 relative to WD0505. In addition, as the wMeiCS genome contains only one copy of Octomom, we confirmed that the Octomom copy number measured was close to one and set its values to exactly 1. We used this transformation of the calibrator value as a standardization for all the samples.

The relative density data were analyzed using general linear models. Normality and homoscedasticity were checked graphically. The data on Octomom copy number were analyzed with general linear models with a gamma distribution, as the distribution of this factor did not fit to a normal distribution. We confirmed graphically that the gamma distribution used in the model fitted to the Octomom copy number data with the package fitdistrplus (Delignette-Muller and Dutang, 2015). The significance of the factors in these models were checked graphically with confidence intervals and considering p-values.

In the first experiment, we focused on the overall effect of the host genetic background on the relative density and Octomom copy number. The host genetic background of the lineages was thus set as the explanatory variable. We used the method of contrasts with p-values adjusted by Tukey method to obtain the pairwise differences between the lineages for both the relative density and the Octomom copy number. To determine the potential role of Octomom in the control of the bacterial population, we estimated the correlation between the relative density and the Octomom copy number (log-transformed data) with a linear model with the average Octomom copy number set as an explanatory variable.

The host genetic background of the lineages was thus set as the explanatory variable. We used the method of contrasts with p-values adjusted by Tukey method to obtain the pairwise differences between the lineages for both the relative density and the Octomom copy number. To determine the potential role of Octomom in the control of the bacterial population, we estimated the correlation between the relative density and the Octomom copy number (log-transformed data) with a linear model with the average Octomom copy number set as an explanatory variable.
In the second and third experiments, we focused on the differences between replicates. Then, the replicate label was set as the explanatory factor. The statistical analyses were performed independently for the Bolivia and USA host genetic backgrounds. We also used the method of contrasts with p-values adjusted by Tukey method to obtain the pairwise differences between the replicates for both the relative density and the Octomom copy number. We finally estimated the correlation between the relative density and the Octomom copy number (log-transformed data) in a linear model with the average Octomom copy number set as an explanatory variable. We performed these correlation analyses: 1) for each genetic background, separately for each timepoint, and 2) for each replicate line, with all timepoints grouped.
Results

To characterize the determinisms at play in the regulation of bacterial density, we first investigated if host genetic background can have an active influence on density levels. As the Octomom region is also implied in density regulation, we additionally tested the influence of its amplification on density levels and the potential interaction between host and bacterial genotypes on density levels.

Wolbachia introgression within various Drosophila melanogaster lines is associated with contrasted infection patterns

During a preliminary experiment, we checked the infection status of six D. melanogaster populations with contrasted genotypes, introgressed with the heterogeneous strain wMelPop originating from the same isoA3 line. When we quantified the relative Wolbachia density (Figure 2A) and the average copy number of the genomic region Octomom (Figure 2B) after the introgression protocol, we found contrasted infection patterns in the different D. melanogaster lines tested.

Both Wolbachia density and composition (i.e., measured as the mean number of Octomom copies per Wolbachia) varied significantly among introgressed lines (Linear regression model; w1118 – MP; Population effect on relative density: P = 2.33 x 10^-20; Population effect on Octomom copy number: P = 2.19 x 10^-22; see statistical details in Table s2). Introgressed lines differed from each other (see pairwise comparisons in Table s3), with a maximum difference in bacterial density and mean Octomom copy number per Wolbachia of respectively 8.3 and 5.8-fold between Bolivia and USA lines (Table s2).

Figure 2: Infection patterns after introgression of Wolbachia in different host genetic backgrounds.

We observed a positive relationship between the relative density per line and its associated mean Octomom copy number per Wolbachia [Intercept = 2.40, SE(Intercept) = 0.75, slope = 0.77, SE(slope) = 0.27, r^2 = 0.8], Linear regression model on median of each host genetic background : P = 0.005 (Figure 3). This strong correlation suggests that variation in the number of Octomom copies is a genetic mechanism involved in the control of bacterial density and confirms previous results highlighted by Chrostek et al. (2013). The number of Octomom repeats could thus provide a way to monitor the evolution of bacterial populations across generations and to better characterize selective pressures associated with the control of bacterial populations.
Figure 3: Relationship between the relative wMelPop density (log) and the average Octomom copy number per Wolbachia cell (log). Median ± SE. Each color represents a host genetic background (n = 10 flies / background), and the dashed line represents the linear regression. 

To summarize, we observed in this preliminary experiment a large variation of Wolbachia densities between the 6 lines of Drosophila melanogaster introgressed with the same wMelPop line—densities that were strongly correlated to the average Octomom copy number per Wolbachia. These results are consistent with the selection of specific variants by different host genetic backgrounds. However, other factors, like genetic drift by founder effect during the vertical transmission of symbionts from the donor line and / or from one host generation to another, could explain this pattern. To disentangle these hypotheses, we thus performed two sets of experiments using the two lines that exhibited the most extreme patterns of infection in the preliminary experiment (i.e., Bolivia and USA).

The infection pattern can change rapidly over generations, regardless of the host genetic background

In the first set of experiments, we performed a similar introgression of the wMelPop Wolbachia strain in the Bolivia and USA genetic backgrounds, but established three independent replicate lines for each host background (Bolivia-MP2 and USA-MP2). While the three replicates should exhibit the same response under host control, variation among the three replicates is expected under the drift hypothesis. We additionally evaluated the stability of the infection pattern over generations, by tracking the relative Wolbachia density (Figure 4A) and the average Octomom copy number per Wolbachia (Figure 4B) immediately after the first introgression event, after 13 generations, and after 25 generations (see Tables S4 & S5 for details).

Figure 4: Replicability of the infection patterns after a new introgression procedure and their evolution over generations. 4A: relative Wolbachia density (log; median ± SE), 4B: average Octomom copy number per Wolbachia (log; median ± SE), n = 6 / line / timepoint. Each color represents a host genetic background. Plain lines represent the replicate lineages from the new introgression procedure (MP2), 13, 12 and 13 indicating the replicates. Dashed lines represent the lineages from the initial introgression procedure (MP1), which were set as reference, in the statistical analyses.

Just after the introgression event (t = 1), the relative Wolbachia density and the average Octomom copy number per Wolbachia did not differ significantly between the Bolivia-MP2 replicate lines and the Bolivia-MP1 line from the first experiment used here as the reference (Linear regression model; experiment group effect on relative density: P > 0.1; experiment group effect on Octomom copy number: P > 0.1; see statistical details in Table S4). The relative density and Octomom copy number in Wolbachia from the Bolivia-MP2 replicate lines did not differ significantly between replicates (see pairwise comparisons in Table S5), which does not contradict a host determination for density regulation through Octomom copy number selection in this genetic background. However, at the same timepoint (t = 1), the relative density and the average Octomom copy number in Wolbachia from the USA-MP2 replicate lines tended to differ from the USA-MP1 line from the first experiment used here as the reference (Linear regression model; experiment group effect on relative density: P = 0.08; experiment group effect on Octomom copy number: P = 0.025; see statistical details in Table S4). The relative density and the average Octomom copy number in Wolbachia from the USA-MP2 replicates lines did not differ between replicates (see pairwise comparisons in Table S5) and the number of octomom copies per Wolbachia did not show significant difference with the donor line (w1118-MP) (Linear regression model; maternal transmission effect on Octomom copy number: P = 0.12; see statistical details in Table S4). The relative density and the average Octomom copy number in Wolbachia from the USA-MP2 replicates lines did not differ between replicates (see pairwise comparisons in Table S5) and the number of octomom copies per Wolbachia did not show significant difference with the donor line (w1118-MP) (Linear regression model; maternal transmission effect on Octomom copy number: P = 0.12; see statistical details in Table S4).
We then examined the stability of the infection pattern over generations, for each replicate line (Figure 4). After 25 generations post introgression, the relative density and Octomom copy number per Wolbachia in Bolivia-MP2 and USA-MP2 replicate lines differed significantly from the quantities measured immediately after introgression (Linear regression model; generational effect on relative density: \( P_{\text{USA-MP2}} = 6.22 \times 10^{-5} \), \( P_{\text{Bolivia-MP2}} = 6.23 \times 10^{-5} \); generational effect on Octomom copy number: \( P_{\text{USA-MP2}} = 7.25 \times 10^{-4} \), \( P_{\text{Bolivia-MP2}} = 0.005 \); see statistical details in Table s4). Moreover, the infection patterns between the Bolivia-MP2 or between the USA-MP2 replicate lines significantly differed (see pairwise comparisons in Table s5).

Finally, we noticed that the correlation between the bacterial density and the average number of Octomom copies per Wolbachia remained high over generations (R\(^2\) = 71%, Figure 5A) and within lines, when variation in Wolbachia density was observed (Figure 5B and associated statistics).

All together, these results show an absence of host control on the density and composition of the bacterial population, and an influence of the number of Octomom copies on the control of Wolbachia densities. The variations observed between replicate lines and over time may thus reflect drift.

The bacterial composition initially transmitted strongly influences the patterns of infection observed over generations. In the second set of experiments, we performed reciprocal crosses to test the respective influence of the host genetic background, the bacterial population, the maternal effect of transmission, and drift on the wMelPop proliferation within flies (experiment #3). In order to jumble the host-Wolbachia associations, we made reciprocal crosses in 3 independent replicates using the Bolivia-MP1 and USA-MP1 line from the first experiment. Then, to evaluate the stability of the infection pattern over generations, we measured the relative density of wMelPop (Figure 5A & 5B) and the average Octomom copy number per Wolbachia per fly (Figures 5C & 5D) one generation after the final homogenizing cross, 13 generations and 25 generations post introgression (see Tables 6 & 7 for details).

Just after the introgression event (t = 1), the relative density and the average Octomom copy number per Wolbachia differed significantly between the Bolivia(USA-MP1) replicate lines and the Bolivia-MP1 line (Linear regression model, experiment group effect on relative density: \( P = 0.047 \); experiment group effect on Octomom copy number: \( P = 4.28 \times 10^{-5} \); see statistical details in Table s6), but not from the USA-MP1 line (Linear regression model, experiment group effect on relative density: \( P = 0.786 \); experiment group effect on Octomom copy number: \( P = 0.586 \); see statistical details in Table s6). In addition, the infection patterns of the Bolivia (USA-MP1) replicate lines did not differ significantly between them (see pairwise comparisons in Table s7). Similarly at the same timepoint, the relative density and the average Octomom copy number per Wolbachia from the USA(Bolivia-MP1) replicate lines differed significantly from those from the USA-MP1 line (Linear regression model, experiment group effect on relative density \( P = 0.018 \); experiment group effect on Octomom copy number \( P = 6.31 \times 10^{-4} \); see statistical details).
Discussion

in Table s6), but not from the Bolivia-MP1 line (Linear regression model, experiment group effect on relative density: \( P = 0.416 \), experiment group effect on Octomom copy number: \( P = 0.559 \), see statistical details in Table s6). In addition, the infection patterns of the USA(Bolivia-MP1) replicate lines did not differ significantly between them (see pairwise comparisons in Table s7). These results confirm an absence of control from the host on the establishment of the infection pattern and rather suggest a homogeneous symbiont transmission from the donor line.

Figure 5: Evolution of infection patterns after reciprocal crosses.

SA. Relative density (log) one generation post introgression (box plot with ‘minimum’, 1st quartile, median, 3rd quartile, and ‘maximum’ ± outliers (dots)). SB. Evolution of the relative density (log) over generations (median ± SE), SC. Average Octomom copy number per Wolbachia line one generation post introgression, SD. Evolution of the average Octomom copy number per Wolbachia line over generations (median ± SE). TE. Evolution of the average Wolbachia copy number per Wolbachia line over generations (median ± SE). Each color represents a host genetic background and the information in brackets represents the bacterial genetic background. Plain lines represent the replicate lines from the reciprocal crosses, L1, L2 and L3 indicating the replicates. Dashed lines represent the lines from the initial introgression procedure (MP1), which was used as reference in the statistical analyses.

Then, we examined whether the infection patterns were stable within each of the replicate lines over generations by measuring the relative density and average Octomom copy number per Wolbachia 13 and 25 generations after the last backcross. After 25 generations post introgression, the relative density in BolivianUSA-MP1 replicate lines differed significantly from their reference at \( t = 1 \) (Linear regression model, generational effect on the relative density: \( P = 0.015 \), generational effect on the Octomom copy number: \( P = 7.79 \times 10^{-4} \), see statistical details in Table s6). On the contrary, the USA(Bolivia-MP1) replicate lines did not differ from their reference at \( t = 1 \) (Linear regression model, generational effect on the relative density: \( P = 0.052 \), generational effect on the Octomom copy number: \( P = 0.259 \), see statistical details in Table s6). Moreover, the infection patterns of the BolivianUSA-MP1 replicate lines differed significantly from each other, as did the infection patterns of the USA(Bolivia-MP1) replicate lines (see pairwise comparisons in Table s7). All together, these results confirm an absence of host control on the density and composition of the bacterial population. Moreover, the variability observed between the replicates indicates a random transmission of the symbiont over generations.

Finally, we confirmed that the correlation between the bacterial density and the average number of Octomom copies per Wolbachia remained high over generations (\( R^2 > 83\% \), Figure 5A) and within the lines, when variation in Wolbachia density was observed (Figure 5C and associated statistics).

In conclusion, we failed to reveal any influence of the host genotype on the control of the wMelPop proliferation through the selection of bacteria containing high or low Octomom copy number. Instead, we found a strong maternal effect of transmission and an instability of the infection patterns over generations. These experiments lead us to consider that drift could be an important evolutionary force responsible for the diversification of infection patterns observed.

\[ \text{Discussion} \]
In this study we sought to identify the determinisms involved in the regulation of endosymbiotic populations and used the Drosophila melanogaster – wMelPop symbiotic system to track the influence of host and symbiont genotypes on the density regulation, as well as the evolutionary forces at play. Indeed, this symbiotic model is particularly relevant because it exhibits genetic variability among the population of vertically transmitted symbiont, whose evolution can be tracked by a genomic amplification (Octomom). While we first found large differences when comparing infection patterns (i.e., bacterial density and average Octomom copy number per Wolbachia) in different host genetic backgrounds, such host control on bacterial proliferation/selection was not confirmed after new experiments of introgression on more replicate lines and crossing experiments between lines exhibiting the most extreme infection patterns. Instead, we showed that the infection patterns were initially set up by the bacterial genotype and became very unstable over generations. These results suggest that, in this symbiotic system, drift strongly influences the evolution of the symbiont density -and thus its stability over generations-, contrarily to what is generally described in the literature of insect endosymbioses [e.g., Mouton et al., 2003; Hosokawa et al., 2006].

Numerous examples in insects support an active regulation of symbiotic populations by the host, with stable density over generations when the environment remains constant [Ikeda, Ishikawa and Sasaki, 2003; Mouton et al., 2004, 2007; Funkhouser-Jones et al., 2018]. The orchestrated modulation of the symbiont proliferation rate throughout insect development also suggests a fine-tuned host control of the bacterial density [Rio et al., 2006; Login et al., 2011; Vigneron et al., 2011]. On the opposite, bacterial factors alone can also explain variation in bacterial densities within some hosts. For example, different strains of Wolbachia are known to exhibit different, but stable, density levels in the same host lines based on their genetic particularities [Mouton et al., 2003; Chrostek et al., 2013].

Proliferation of symbionts within the host is under strong selection as it is a key factor influencing the trade-off between symbiont transmission (i.e., the higher the symbiont density, the higher the probability of transmission) and virulence (i.e., the higher the symbiont density, the higher the cost on host survival and fecundity) [Anderson and May, 1982; Ewald, 1983]. This transmission/virulence trade-off often leads to an optimal density, which can be controlled by host or bacterial determinants. In insect hosts, the main molecular mechanisms that determine the abundance and composition of symbionts are associated with immune response [Lemaitre and Hoffmann, 2007; Zub and Hammerstein, 2015] or resource allocation [Kiers et al., 2003]. Microbial communities can in turn select resistance mechanisms against host effectors or trigger antagonist regulators of the host immunity (Vallet-Gely et al., 2008; Lindsey, 2020).
levels. However, the genomic region 'Octomom' has recently been questioned regarding its involvement in the establishment of density levels. Initially, it has been shown that proliferation rate and virulence of wMelPop are correlated with genomic amplification of the Octomom region (Chrostek et al., 2013; Chrostek and Teixeira, 2015, 2018), but this relationship has been challenged by Rohrscheib and her collaborators (Rohrscheib et al., 2016, 2017), who support that the virulence of wMelPop rather depends on an increase in the extrinsic rearing temperature. However, to exclude any influence of the Octomom copy number on Wolbachia growth and pathogenicity, these variables should be tested independently of the temperature (Chrostek and Teixeira, 2017).

At constant temperature, our results show a clear link between Wolbachia density in adults and the average number of Octomom copies per Wolbachia, and are in accordance with the current literature (Chrostek et al., 2013; Chrostek and Teixeira, 2015, 2018; Monnin et al., 2020). While we cannot exclude that another gene or set of Wolbachia genes different from Octomom could determine symbiont density, the strong correlation between the density observed and the number of Octomom repeats in all the experiments (generally >80% when the density was variable) suggests that Octomom is the main determinant of bacterial density in this biological system and in our controlled conditions. Consequently, this genomic amplification can be used as a marker of bacterial diversity and evolution of our experimental system.

We can thus wonder why we observed such variability and temporal instability within lineages, and why drift overcome this potential bacterial regulation through Octomom? Indeed, this pattern contrasts with what is observed in already well-established symbioses, where one symbiont genotype is fixed (Werren, Baldo and Clark, 2008). In our experiments, we were able to show very similar levels of infection between mothers and daughters just after introgression or reciprocal crosses procedures, suggesting a maternal effect. However, instability detected across generations suggests that this maternal effect is probably non-genetic: when a large number of bacteria is quantified in the mother’s tissues, a large number of bacteria is transmitted to the oocytes and maintained in the adult stage (Veneti et al., 2004; Hosokawa, Kikuchi and Fukatsu, 2007; Parkinson, Gobin and Hughes, 2016). However, there may be still random variability between mothers regarding the amount of bacteria transmitted to their eggs, and between these eggs (Mira and Moran, 2002). Bottlenecks during transmission can thus eventually lead to a gradual shift of the ‘initial’ density over time. Bottlenecks can also influence density levels through random differential transmission of bacterial variants from one generation to the next (Funk, Wernegreen and Moran, 2001; Kaltenpoth et al., 2010), especially if these variants exhibit different reproductive rates (as it is the case with variants carrying different numbers of Octomom copies (Duarte et al., 2021)). To summarize, if not counteracted by host or symbiont density control, drift is expected to induce instability over generations by a combination of quantitative (i.e., transmission of a non-equivalent number of bacteria to the eggs) and qualitative/genetic (i.e., random transmission of different variants) bottlenecks. Hence, the high variability and the temporal instability depicted in our study could reflect the random transmission of different wMelPop quantities and variants during transmission bottlenecks. In addition, drift at the transmission level alone cannot explain variation of the average density at the population level, but should be associated to other factors. Drift at the host population level could play a role by fixing hosts with symbiotic populations with a different average of Octomom copy number. Alternatively, selection, or mutation bias could also play a role. For instance, the mutation rate of a repeated sequence in microsatellites...
can strongly depend on the number of motifs present in the sequence (Whittaker et al., 2003). Assuming the same rules on the number of Octomom copies present in the population (i.e., a higher propensity for duplication when the number of copies is high), the outcomes of drift could be more unpredictable for individuals harboring the highest average number of Octomom copies. Indeed, in the presence of moderate bottlenecks and a mutation rate increasing with the number of copies, a strong variability of infection patterns is expected over generations. However, we did not observe such higher temporal instability when the values of density and Octomom copy numbers were high in the donor lines. These results suggest that the influence of the mutation rate was negligible compared to the transmission bottleneck. Under conditions of genetic instability linked to transmission bottlenecks, between-host selection should not be efficient, and would explain why the vertically transmitted wMelPop strain exhibits a strong virulence, whereas the overall alignment of interests between the host and vertically transmitted symbionts generally leads to the selection of low virulent symbionts that maximize host survival and indirectly their own transmission (Anderson and May, 1982; O’Neill, Hoffmann and Werren, 1997).

Different environmental conditions can also modify the optimum density of the symbiont. Optima can be different for the host and the symbiont, and lead to antagonistic interactions between symbiotic partners and to variations in bacterial density (Parker et al., 2021). In the D. melanogaster / wMelPop system, the maintenance of the virulence phenotype has thus frequently been associated with the fact that virulence is only expressed in conditions rarely observed in nature, so that the between-host selection against highly prolific variants (such as those with high Octomom copy numbers) is weak at 25°C. A recent study however shows that strains with 8-9 Octomom copies are pathogenic from 18°C to 29°C (Duaire et al., 2021). In addition, another selective force, the within-host selection, could explain the virulence of wMelPop in certain environmental conditions. Indeed, when fly populations are reared at 28°C, Monnin et al. (2020) showed that the population evolved toward a higher virulence, which may be due to the stronger effect of within-host selection compared to between-host selection. Thus, when selective pressures are strong, within and between-host selection could modulate symbiont virulence in the Drosophila-wMelPop association, whereas drift might not allow any co-evolution between partners and co-adaptation to environmental changes when selective pressures are limited.

To conclude, we showed that the host did not control for bacterial density and composition in the symbiosis between D. melanogaster and wMelPop, and that the infection patterns were very instable across generations, suggesting a strong influence of drift that could limit the effects of within- and between-host selections. As the transmission of symbionts in vertically-transmitted symbiosis is subject to potential bottlenecks both in terms of quantity and genetic diversity (Mira and Moran, 2002; Galbreath et al., 2009; Kaltenpoth et al., 2010), it seems necessary to further characterize the intensity of bottlenecks in this symbiotic system, in order to better evaluate the impact of drift on the evolution of bacterial populations in vertically transmitted symbiosis and its impact on host phenotypes.
