Abstract

Whether the malaria parasite *Plasmodium falciparum* can manipulate mosquito host choice in ways that enhance parasite transmission toward human is unknown. We assessed the influence of *P. falciparum* on the blood-feeding behaviour of three of its major vectors (*Anopheles coluzzii*, *An. gambiae* and *An. arabiensis*) in Burkina Faso. Host preferences assays using odor-baited traps revealed no effect of infection on mosquito long-range anthropophily. However, the identification of the blood meal origin of mosquitoes showed that females carrying sporozoites, the mature transmissible stage of the parasite, displayed a 24% increase in anthropophagy compared to both females harbouring oocysts, the parasite immature stage, and uninfected individuals. Using a mathematical model, we further showed that this increased anthropophagy in infectious females resulted in a > 250% increase in parasite transmission potential, everything else being equal. This important epidemiological consequence highlights the importance of vector control tools targeting infectious females.

Introduction

There is mounting evidence that malaria parasites affect phenotypic traits of their vectors and hosts in ways that increase contacts between them, hence favouring parasite transmission (Hurd 2003, Koella 2005, Lefèvre and Thomas 2008). In addition to increased vertebrate attractiveness to mosquito vectors (Lacroix *et al.* 2005, Cornet *et al.* 2013, Batista *et al.* 2014, De Moraes *et al.* 2014, Busula *et al.* 2017, Emami *et al.* 2017), another frequently reported parasite-induced change is the alteration of vector motivation and avidity to feed (Cator *et al.* 2012, Stanczyk *et al.* 2017). Mosquitoes infected with *Plasmodium* sporozoites (the mosquito to human transmission stage) can indeed display increased (i) response to host odours (Rossignol *et al.*

1986, Cator *et al.* 2013), (ii) landing and biting activity (Rossignol *et al.* 1984, Rossignol *et al.* 1986, Wekesa *et al.* 1992, Anderson *et al.* 1999, Koella *et al.* 2002, Smallegange *et al.* 2013), (iii) number of feeds (Koella *et al.* 1998) and (iv) blood volume intake (Koella and Packer 1996, Koella *et al.* 1998, Koella *et al.* 2002). In contrast, mosquitoes infected with oocysts (the immature non-transmissible stage of the parasite), are less likely to attempt to feed (Anderson *et al.* 1999, Koella *et al.* 2002, Cator *et al.* 2013). Since biting is risky (e.g., host defensive behaviours can kill the vector and its parasite), reduced feeding attempts would be beneficial to the parasite during the non-transmissible stage as this would reduce mortality before the parasite reaches maturity and is ready to be transmitted (Schwartz and Koella 2001).

These "stage-dependent" behavioural alterations likely increase parasite transmission (Dobson 1988, Cator *et al.* 2014), provided that mosquito feeds are taken on a suitable vertebrate host species for the parasite. While malaria vectors can usually feed on a range of different vertebrate species (Takken and Verhulst 2013), the malaria parasites they transmit are often highly host-specific, infecting only one or a few vertebrate species (Perkins 2014). For example *P. falciparum*, which causes the most severe form of human malaria, displays an extreme form of specificity and can develop and reproduce in hominids only (predominantly in human and to a lesser extent in chimpanzee, bonobo, and gorilla) (Prugnolle *et al.* 2011, Rayner *et al.* 2011, Ngoubangoye *et al.* 2016), such that any mosquito bite on another vertebrate species would be a dead-end for the parasite. In contrast, the vectors of *P. falciparum* can feed on a wide range of vertebrate hosts species in the wild depending on the geographic area and the relative abundance of human and other vertebrates (Costantini *et al.* 1999, Takken and Verhulst 2013). Accordingly, *P. falciparum* could modify its vector choice in ways that enhance transmission toward human and/or reduce mosquito attraction to other unsuitable host species (i.e. specific manipulation). A

previous study testing this hypothesis found no effect of *P. falciparum* infection on host preference of three major vector species, *An. coluzzii*, *An. gambiae*, and *An. arabiensis* (Nguyen *et al.* 2017). However, this study examined the odour-mediated mosquito host preference in laboratory conditions using a dual-port olfactometer, not the final realised host choice which is of primary importance for parasite transmission.

Here, we assessed the influence of *P. falciparum* on *An. coluzzii*, *An. gambiae* and *An. arabiensis* blood-feeding behaviour in three villages of Burkina Faso. First, odor-baited traps, set side by side in a choice arrangement and releasing either human or calf odors were used to determine odour-mediated mosquito host preference (Experiment 1). Second, indoor-resting blood-fed mosquito females were collected and the origin of their blood meal was identified to determine mosquito host selection (Experiment 2). Third, we quantified the epidemiological consequences of variation in the patterns of host selection using a compartmental model for *Plasmodium* transmission between humans and mosquitoes.

Material and methods

Collection sites

The study was conducted in three villages of South-Western Burkina Faso: Soumousso (11°23'14"N, 4°24'42"W), Klesso (10°56'40.5"N, 3°59'09.9"W) and Samendeni (11°27'14.3"N, 4°27'37.6"W) (Figure supplement S1). The three villages are located in an area characterized by wooded savannah, where *Anopheles* females only have access to temporary, rain-filled puddles and quarries that permit larval development during the rainy season from June to November. The dry season extends from December to May. In these rural villages, domestic animals (including cattle, goats, sheep, pigs, chickens, donkeys, dogs) are usually kept in

compounds in open conditions but a few households use separate roofed shelters for sheep, goats, pigs and chicken. Most houses are mud-walled with roofs of iron sheets or thatch, but a few houses are made of bricks.

***Experiment 1*: Mosquito host preference**

Two odour-baited entry traps (OBETs as in Costantini *et al.* 1996, Costantini *et al.* 1998, Lefèvre *et al.* 2009) and two odour-baited double net traps (BNTs as in Tangena *et al.* 2015) baited with calf and human odours were used to assess the host preference of field populations of mosquitoes in Samandeni and Klesso villages (Figure 1).The two OBETs were connected to a tent (Lxlxh: 250x150x150 cm) by air vent hoses (Scanpart®, DxL=10*300cm; Figure 1a). The odours of the two hosts were drawn by a 12-V fan from the tents and into the OBETs by the air vent hoses, coming out of the traps at a speed of 15cm/s (±2cm/s), as measured with a Testo 425-Compact Thermal Anemometer (Testo, Forbach, France) equipped with a hot wire probe [range: 0 to + 20m/s, accuracy: ± (0.03 m/s + 5% of mv)]. Host-seeking mosquitoes responding to the host cues flew up the odour-laden streams and entered one of the two traps. The two odour-baited double net traps (BNTs) consisted of an untreated bed net (Lxlxh: 300x250x185 cm) from which each corner was raised 20 cm above ground and a smaller untreated bed net (Lxlxh: 190x120x150 cm) protecting the human volunteer in the human baited trap (Figure 1b).

In both OBETs and BNTs, the human volunteers rested on a metal-framed bed (Lxl: 190x80 cm) and were protected from mosquito bites. OBETs and BNTs were operated from 19:00 to 05:30 hours, for 3 nights in June 2013, and 13 nights in September 2013 in Samendeni. The BDNTs only were set-up for 6 nights in September in Klesso. Different combinations of live calves and humans were used as odour sources on each testing day to obviate any individual effect. Calves of about similar size and weight as human volunteers were used to equalize

quantity of emitted odours. Trapped mosquitoes were retrieved in the morning using mouth aspirators. They were kept in a 20x20x20 cm cage with a humid towel on top and brought back to the laboratory for further processing (see below).

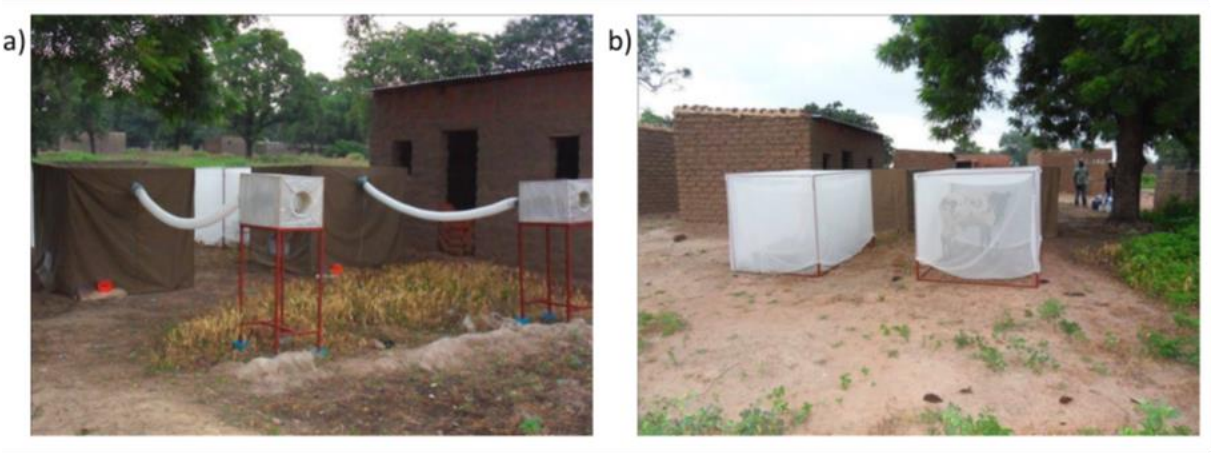

Figure 1. Traps baited with calf and human odours used to assess the host preference of field populations of mosquitoes in Samandeni and Klesso villages. **a)** Two odor-baited entry traps (OBETs) were connected to a tent by air vent hoses. **b)** Two odor-baited double net traps (BNTs).

Experiment 2: Mosquito blood-feeding pattern

Indoor resting blood-fed mosquitoes were collected between 7 am and 9 am by insecticide spray catches as in Lefèvre et al. (2009) to determine the origin of their blood-meal. Briefly, white sheets were spread over the floor surface and the furniture inside houses. The houses were then sprayed with an insecticide (Kaltox®: allethrin 0.27%, tetramethrin 0.20 %, permethrin 0.17%, propoxur 0.68%) to knock down the mosquitoes. Fifteen minutes after spraying, blood-fed *An. gambiae s.l.* mosquitoes were collected from the white sheet using forceps and placed on moist filter paper inside labeled petri dishes.

In Samandeni and Klesso, mosquito collections were carried out in the rainy season only (4 days in June 2013, and 13 days in September 2013 in Samendeni, and 6 days in September 2015 in Klesso), whereas in Soumousso it was conducted in both the rainy and the dry season (26 days between January and November 2009). In Soumousso, human dwellings (from 10 neighbourhoods) only were sampled whereas animal sheds and unoccupied houses were also sampled in Samandeni and Klesso. A total of 27 human dwellings, 7 unoccupied houses and 20 animal sheds were sampled in Samendeni. A total of 7 human dwellings, 7 unoccupied houses and 9 animal sheds were sampled in Klesso. All mosquitoes were kept in petri dish with a humid paper towel to facilitate later dissection and brought back to the laboratory for further processing (see below).

Laboratory processing of samples

A total of 3447 blood-fed *Anopheles gambiae s.l.* collected indoors (Experiment 2) and 674 females collected in the choice traps (Experiment 1) were processed. In addition, a subset of 276 females collected indoors was used to determine parity (parous versus nulliparous) based on the condition of ovarian tracheoles. Similarly, a subset of 418 individuals was used to distinguish between the *Anopheles* species sensu stricto (*Anopheles arabiensis*, *Anopheles coluzzii* and *Anopheles gambiae*) using routine PCR-RFLP based on segregating SNP polymorphisms in the X-linked ribosomal DNA InterGenic Spacer region as described in Santolamazza *et al.* (2008).

Anopheles gambiae sl. females were dissected in a drop of phosphate buffered saline (PBS) (pH 7.2). Blood-fed midguts were gently squeezed under a stereomicroscope (magnification 35x, Leica EZ4D, Wetzlar, Deutschland) to get the blood out, which was mixed with PBS, absorbed on a filter paper, and then kept at -20°C until identification by an enzyme-

linked-immunosorbent assay (ELISA) for Soumousso and Samendeni samples (Beier *et al.* 1988) and by multiplex PCR as for Klesso samples. Each blood meal was discriminated between human, cattle, goat/sheep, chicken, dog, pig, and horse/donkey origins. ELISA-based determination of mosquito blood meal origin was performed using anti-bovine IgG-peroxidase conjugate (A5295, Sigma-Aldrich), anti-human IgG-peroxidase conjugate (A8794, Sigma-Aldrich), anti-pig IgG-peroxidase conjugate (A5670, Sigma-Aldrich), anti-chicken IgG-peroxidase conjugate (A9046, Sigma-Aldrich), anti-goat IgG-peroxidase conjugate (A5420, Sigma-Aldrich), anti-sheep IgG-peroxidase conjugate (A3415, Sigma-Aldrich), anti-dog IgG-peroxidase conjugate (A6792, Sigma-Aldrich), and anti-horse IgG-peroxidase conjugate (A6917, Sigma-Aldrich). PCR-based determination of the mosquito blood meal origin targeting the vertebrate host cytochrome B was performed as described by Kent and Norris (2005), with the following modifications: *(i)* Three additional primers were designed from available Genbank sequences to target the following potential hosts: chicken470F (Genbank accession number: AB044986.1), sheep695F (KY662385.1), donkey574F (FJ428520.1); *(ii)* for each individual, two multiplex reactions were performed to avoid cross-reactions between primers and to optimize the determination. In the multiplex reaction #1, UNREV1025, Chicken470F, Sheep695F, Goat894F and Donkey574F primers were used at an amplification temperature of 49.2 °C. In the multiplex reaction #2, UNREV1025, Dog368F, Human741F, Cow121F and Pig573F primers were used at an amplification temperature of 58°C. Blood meal origin diagnostic was based on the PCR products expected sizes as follow: donkey (460bp), sheep (340bp), chicken (290bp), goat (150bp), dog (680bp), cow (561bp), pig (453bp), human (334bp).

The extracted midguts were then stained with 1% Mercurochrome® solution to detect with a microscope (magnification 400x, Leica ICC50, Wetzlar, Deutschland) the presence and

number of *Plasmodium* spp. oocysts. PCR on a subset of oocyst-infected individuals (20 midguts of a total of 118 oocyst-infected individuals) confirmed that these oocysts all belonged to *P. falciparum*. Head and thorax of individual mosquitoes were stored at −20°C in 1.5 mL Eppendorf tubes. Sporozoite infection with *P. falciparum* was determined by ELISA using peroxidase-conjugated *Plasmodium falciparum* circumsporozoite protein monoclonal antibody for the Soumousso samples (Wirtz *et al.* 1987) and by qPCR for the samples from Samendeni and Klesso (Boissière *et al.* 2013). The quantification of *P. falciparum* sporozoites in salivary glands was determined by qPCR using 7500 Fast Real time PCR System (Applied Biosystems, Foster City CA, USA). The mosquito heads and thoraxes were crushed individually and DNA extracted as previously described (Morlais *et al.* 2004). For sporozoite quantification, we targeted the fragment of subunit 1 of the mitochondrial cytochrome c oxidase gene (cox 1) using the forward and reverse primer sequences, qPCR-PfF 5'-TTACATCAGGAATGTTATTGC-3' and qPCR-PfR 5'-ATATTGGATCTCCTGCAAAT-3, respectively. The reaction was conducted in a 10µL final volume containing: 1µL of DNA template, 1x HOT Pol EvaGreen qPCR Mix Plus ROX, and 600nM of each primer. Amplification started by initial activation step at 95°C for 15min and 40 cycles of denaturation at 95°C for 15s and annealing / extension at 58°C for 30s. Detection was conducted during the last step (Boissière *et al.* 2013). Quantification was based on a standard curve built from four serial dilutions (12%) of an asexual parasite culture. We made dilutions ranging from 60 to 60,000 genome/µl of DNAs from a standard culture. The first dilution (10^{-1}) was used as a positive control. The standard curve (y= -3.384X +35.874) was obtained by linear regression analysis of Ct values (Cycle threshold) *versus* log10 genome copy number of parasite culture.

This protocol allowed us to gather the following information for each collected individual mosquito: immature *Plasmodium* infection status (presence of oocysts in the midgut); mature *P. falciparum* infection status (presence of sporozoites in salivary glands); source of blood meal or trap (calf/human) chosen; shelter type (human dwellings, unoccupied houses, animal sheds).

Statistical analyses

Mosquito host preference (OBETs and BNTs)

The anthropophily index (AI) was expressed as the number of *Anopheles gambiae s.l.* caught in the human-baited trap over the total number of mosquitoes caught in both human- and calf- baited traps. We tested the effect of infection status (uninfected, infected with the oocyst immature stages and infected with the sporozoite transmissible stages), collection method (OBET vs. BNT), and their interaction on AI using a general linear model (GLM) with a binomial error structure.

Mosquito blood-feeding pattern (blood origin of indoor resting samples)

The human blood index (HBI) was expressed as the number of *Anopheles gambiae s.l.* fed on human including mixed human-animal bloodmeals over the total number of blood-fed *Anopheles gambiae s.l.*. We tested the effect of *Plasmodium* infection status (uninfected, oocyst-infected, sporozoite-infected individuals - 25 individuals with both oocysts and sporozoites were included in the sporozoite infected group and excluding these individuals from the analysis yielded similar results), village (Soumousso, Samendeni, Klesso), shelter type (human dwelling, unoccupied house, animal shed) and relevant two-ways interactions (infection status by shelter type and infection status by village) on HBI using a general linear model (GLM) with a binomial error structure. The effect of species (*Anopheles gambiae*, *An. coluzzii* and *An. arabiensis*),

infection status, shelter type, and their interactions on HBI was assessed using the subset of females identified to the molecular level using a GLM with a binomial error structure. The effect of parity (nulliparous *vs*. parous) on HBI was assessed on a subset of females using a GLM with a binomial error structure.

We also verified for both AI and HBI whether choice significantly differed from a random distribution between humans and animals or whether mosquitoes displayed a statistically significant attraction to one type of blood meal or trap.

For model selection, we used the stepwise removal of terms, followed by likelihood ratio tests (LRT). Term removals that significantly reduced explanatory power ($P<0.05$) were retained in the minimal adequate model (Crawley 2007). All analyses were performed in R v.3.0.3. Results are presented as mean ± standard error (se) and proportion ± confidence interval (CI).

Mathematical model

In order to explore the epidemiological consequences of variation in HBI, we built a compartmental model for *Plasmodium* transmission between humans and mosquitoes (Keeling and Rohani 2008):

$$\frac{dS_m}{dt} = \mu N_m - ab\frac{S_m}{N_m}I_h\varepsilon_s - \mu S_m$$

$$\frac{dE_m}{dt} = ab\frac{S_m}{N_m}I_h\varepsilon_s - (\mu+\gamma)E_m$$

$$\frac{dI_m}{dt} = \gamma E_m - \mu I_m$$

238 $$\frac{dS_h}{dt} = -ac\frac{S_h}{N_h}I_m\varepsilon_i + \delta I_h$$

239 $$\frac{dI_h}{dt} = ac\frac{S_h}{N_h}I_m\varepsilon_i - \delta I_h$$

240 Susceptible mosquitoes (S_m) born at rate μ and become exposed (E_m) according to their biting
241 rate (a), their probability to get infected (b) and the HBI of susceptible mosquitoes (ε_s). Then,
242 exposed mosquitoes become infectious (I_m) according to their extrinsic incubation period (γ).
243 Each mosquito population die at rate (μ). Nm being the number of mosquitoes. Susceptible
244 humans (S_h) get infected according to mosquito biting rate, probability to develop infection (c)
245 and HBI of infectious mosquitoes (ε_i). Nh being the number of humans. Then, infectious humans
246 remain infectious (I_h) during their infectious period equals to $1/\delta$ on average. See parameters
247 values in table supplement S1 (Roux *et al.* 2015, Vantaux *et al.* 2016). We considered in our
248 simulation for HBI of susceptible mosquitoes (ε_s) the confidence interval of oocyst-infected
249 mosquitoes value that has been experimentally measured in this study and we explored the
250 impact of HBI of infectious mosquitoes (ε_i, during the sporozoite stage) on the Entomological
251 Inoculation Rate (EIR, representing the number of infectious bites received by a human during
252 one year (Smith and Ellis McKenzie 2004), as defined by:

253 $$EIR = ma\frac{I_m}{N_m}$$

254 where m is the ratio between mosquitoes and humans, and other parameters are similar as above.
255 With an identical human population size of 100 individuals, we have assumed different ratio
256 values (m) between mosquitoes and humans (low: m=1, medium: m=10 and high: m=100) to
257 explore the impact of different HBIs on the EIR in relation to mosquito densities. Then, the ODE

system has been simulated for one season in order to estimate the proportion of infectious mosquitoes.

Ethics

Ethical approval was obtained from the Centre Muraz Institutional Ethics Committee under agreement no. 0003-2009/CE-CM and A0003-2012/CE-CM.

Results

Experiment 1: Mosquito host preference – To assess the inherent mosquito host preference of field populations of mosquitoes, we used two odour-baited entry traps (OBETs) and two odour-baited double net traps (BNTs) releasing either calf or human odours. The anthropophily index (AI) was expressed as the number of *Anopheles gambiae s.l.* caught in the human-baited trap over the total number of mosquitoes caught in both human- and calf- baited traps. The infection status was successfully determined in 584 out of the 674 mosquitoes (86.6%) collected in the OBETs (383 individuals) and BNTs (201 individuals). Uninfected, oocyst-infected and sporozoite-infected females displayed similar host preferences (X^2_2 = 3.6, P = 0.17, Figure supplement S2,AI uninfected females: 63.3 ± 4%, N=531, OR=0.58, 95% CI = 0.53-0.63, P <0.0001; AI oocyst-infected females: 55.2 ± 18 %, N=29, OR=0.81, 95% CI = 0.56-1.18, P=0.58; AI sporozoite-infected females: 45.8 ± 20 %; N=24, OR=1.18, 95% CI = 0.78-1.78, P=0.7). There was no effect of collection method on AI (OBETs: 64 ± 5%, BNTs: 59 ± 7%; X^2_1 = 1.5, P = 0.21), indicating that both methods are comparable to assess mosquito host preference. There was no interaction between mosquito infection and collection method (X^2_2 = 0.26, P = 0.9; Figure supplement S2).

Experiment 2: Mosquito blood-feeding pattern – To assess the realized host selection of *Anopheles gambiae s.l.*, the blood meal origins of females collected indoors between 7 am and 9 am were identified. The human blood index (HBI) was expressed as the number of females fed on human (including mixed human-animal bloodmeals) over the total number of blood-fed females. Of the 3447 blood-fed *Anopheles gambiae s.l.* collected indoors, the blood meal origin was successfully identified in 2627 samples (76%). Among these 2627 samples, infection status was successfully determined in 2328 mosquitoes (88.6%). The following analyses are restricted to these 2328 females. HBI was significantly affected by mosquito infection status ($X^2_2 = 13.007$, P = 0.0015; Figure 2) with a 24% increase in HBI in sporozoite-infected females compared to both oocyst-infected and uninfected counterparts (sporozoite-infected: 77 ± 5.7%; N=209, deviation from random feeding: OR=0.3, 95% CI = 0.25-035, P <0.0001; oocyst-infected females: 63.6 ± 5.7%, N=118, OR=0.57, 95% CI = 0.47-0.69, P =0.004; uninfected females: 61.1 ± 2.1%; N=2001, OR=0.64, 95% CI = 0.61-0.66, P <0.0001). However, because sample size in the uninfected group (n=2001) was higher than that of both sporozoite-infected (n = 209) and oocyst-infected groups (n=118), we ran a second set of analyses using a subset of 150 randomly selected uninfected individuals. This approach normalizes statistical power to test for statistically significant differences in HBI across heterogeneous sample sets. This analysis confirmed a significantly higher anthropophagy in sporozoite-infected individuals compared to both oocyst-infected individuals and uninfected individuals (X^2_2= 11.6, P= 0.003; Tukey post-hoc tests: sporozoite-infected vs. oocyst-infected individuals, P=0.026; sporozoite-infected vs. uninfected individuals (Tukey post-hoc test: P=0.006; oocys-infected vs uninfected individuals, P= 0.96). The HBI of sporozoite-infected mosquitoes was higher than that of oocyst-infected and uninfected females regardless of the village considered (infection status: village interaction: X^2_4

304 = 2.3, P = 0.68, Figure 2) or the shelter type in which mosquito females were collected (infection
305 status: shelter type interaction: $X^2_4 = 0.7$, P = 0.95, Figure supplement S3).

306 HBI was also significantly influenced by shelter type ($X^2_2 = 145.92$, P < 0.0001). Females
307 collected in animal sheds were significantly less likely to have fed on human host (22.3 ± 4%)
308 than females collected in unoccupied houses (40.9 ± 6.8%; Chi-square post-hoc test: $X^2_1 = 21.6$,
309 P < 0.0001) or in human dwellings (74.5 ± 2%; Chi-square post-hoc test: $X^2_1 = 385$, P < 0.0001).
310 Females collected in human dwellings were also significantly more likely to have fed on human
311 host than females collected in unoccupied houses (Chi-square post-hoc test: $X^2_1 = 96$, P <
312 0.0001). HBI was significantly affected by the village ($X^2_2 = 139.5$, P < 0.0001). However, in
313 Soumousso human dwellings only were sampled confounding the effect of village and shelter
314 type in this case. Therefore, we carried out an analysis on the human dwellings only to compare
315 HBIs in the three villages. Mosquitoes were significantly less anthropophagic in Samendeni
316 (56.5± 4%), compared to Soumousso (83.5±2.2%; Chi-square test: $X^2_1 = 138.8$, P < 0.0001) and
317 Klesso (77.3±9 %; Chi -square test: $X^2_1 = 12.7$, P = 0.0004). HBIs in Soumousso and Klesso
318 were not significantly different (83.5±2.2% *vs*. 77.3±9 % respectively; Chi-square test: $X^2_1 = 1.8$,
319 P = 0.18).

320

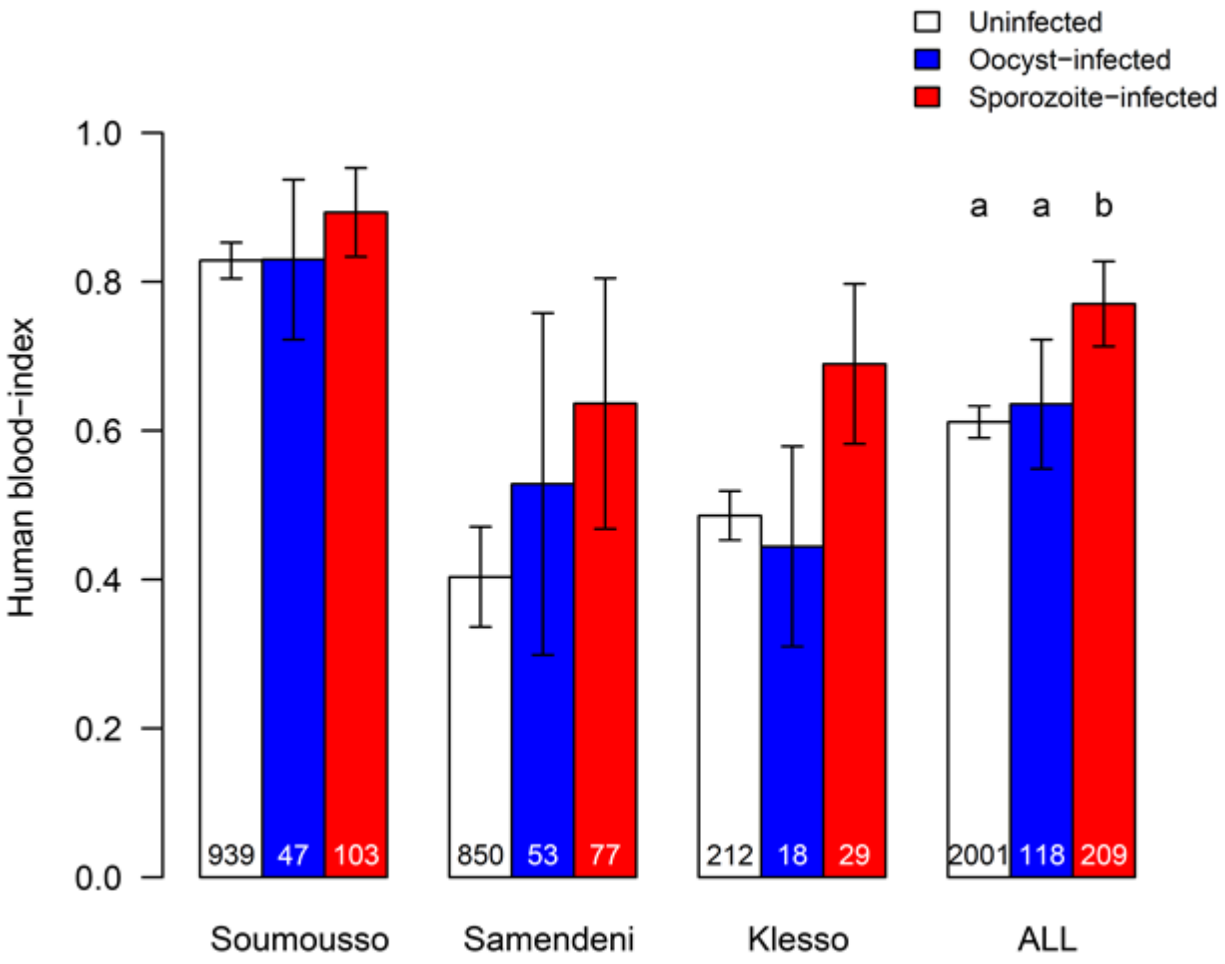

Figure 2. Effect of infection status on the human-blood index of *Anopheles gambiae s. l.* females expressed as the number of females fed on human out of the total number of blood-fed females for the three sampled villages. Data show proportion ± 95% confidence interval. Numbers in bars indicate the total numbers of mosquitoes. Different letters indicate differences between infection status (Chi-square *post-hoc* tests: sporozoite-infected *vs.* oocyst-infected females X^2_1=6.1, P=0.013; sporozoite-infected *vs.* uninfected females X^2_1=19.4, P<0.0001; oocyst-infected *vs.* uninfected females X^2_1=0.18, P= 0.67).

A significant species variation in HBI was observed (X^2_2 = 10.2, P = 0.006; Figure 2) with *Anopheles arabiensis* being significantly less anthropophagic (22.2 ± 15%, N=27, OR=3.5,

95% CI = 2.2-5.56, P = 0.007) than *An. gambiae* (54.8 ± 7.1%; N=186, OR=0.82, 95% CI = 0.71-0.95, P = 0.19) and *An. coluzzii* (55.1 ± 6.8%; N=205, OR=0.81, 95% CI = 0.71-0.94, P=0.14). Although HBI varied among mosquito species, sporozoite-infected individuals displayed highest anthropophagy regardless of the species considered (infection status: species interaction: $X^2_4 = 4$, P = 0.42; Figure 3 and supplementary material).

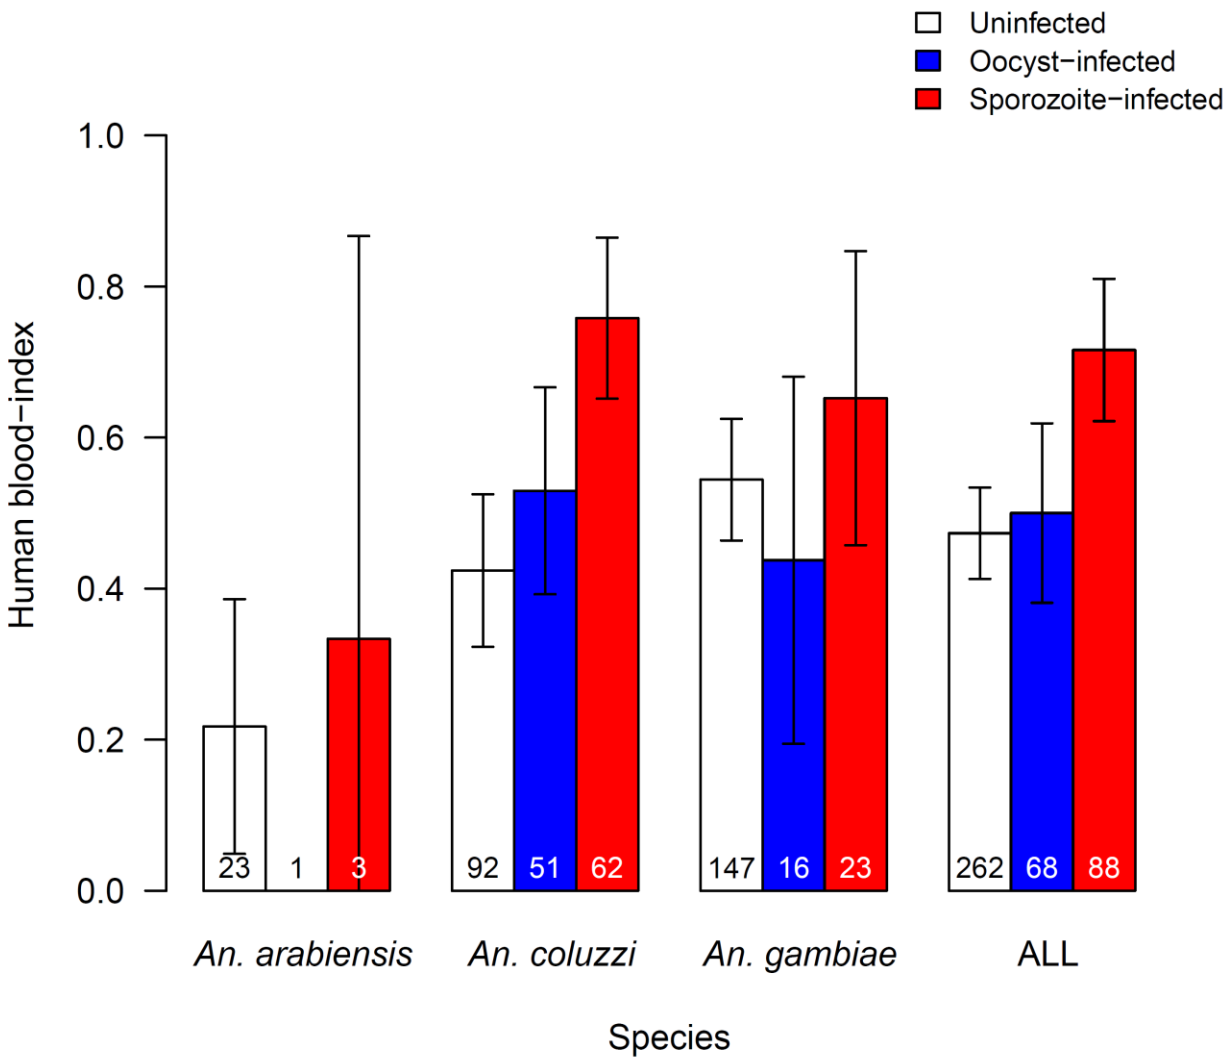

Figure 3. Effect of infection status and *Anopheles* species *sensu stricto* on the human-blood index expressed as the proportion of females fed on human or human and animal out of the total

of blood-fed females. Data show proportion ± 95% confidence interval. Numbers in bars indicate the total numbers of mosquitoes.

Finally, HBI was not significantly affected by parity, a proxy used to estimate mosquito age (nulliparous females: 49.53 ± 9%, parous females: 45.6 ± 7.5%; $X^2_1 = 0.4$, P = 0.52)

Epidemiological consequences – To investigate the epidemiological impact of a higher HBI in infectious females compared to oocyst-infected and uninfected females, we built a mathematical model based on the experimental values observed in this study. This model assessed the impact of different HBIs on the Entomological Inoculation Rate (EIR, number of infectious bites received by a person during one year) at different mosquito longevities and densities. The HBI of susceptible mosquitoes was fixed at 0.62 (as in uninfected and oocyst-infected mosquitoes) and the impact of HBI variation in infectious (sporozoite-infected) mosquitoes on parasite transmission potential was explored (Figure 4). For an average mosquito lifespan of 15 days (Figure 4a), an HBI of infectious mosquitoes of 0.62 (similar to that of susceptible mosquitoes) resulted in an EIR of 4 at a low ratio of 1 (1 mosquito per human), while an HBI of 0.77 (as observed here in infectious mosquitoes) resulted in an EIR of 14. In other words, a 24% increase in HBI resulted in a 250% increase in EIR, everything else being equal. Transmission consequences were even larger when the human-to-mosquito ratios were higher (5 *vs*. 19 with a ratio of 10 or 100, i.e. a 280% increase in EIR) but tended to decrease with increasing mosquito longevities (Figure 4c, 4d, and supplementary material).

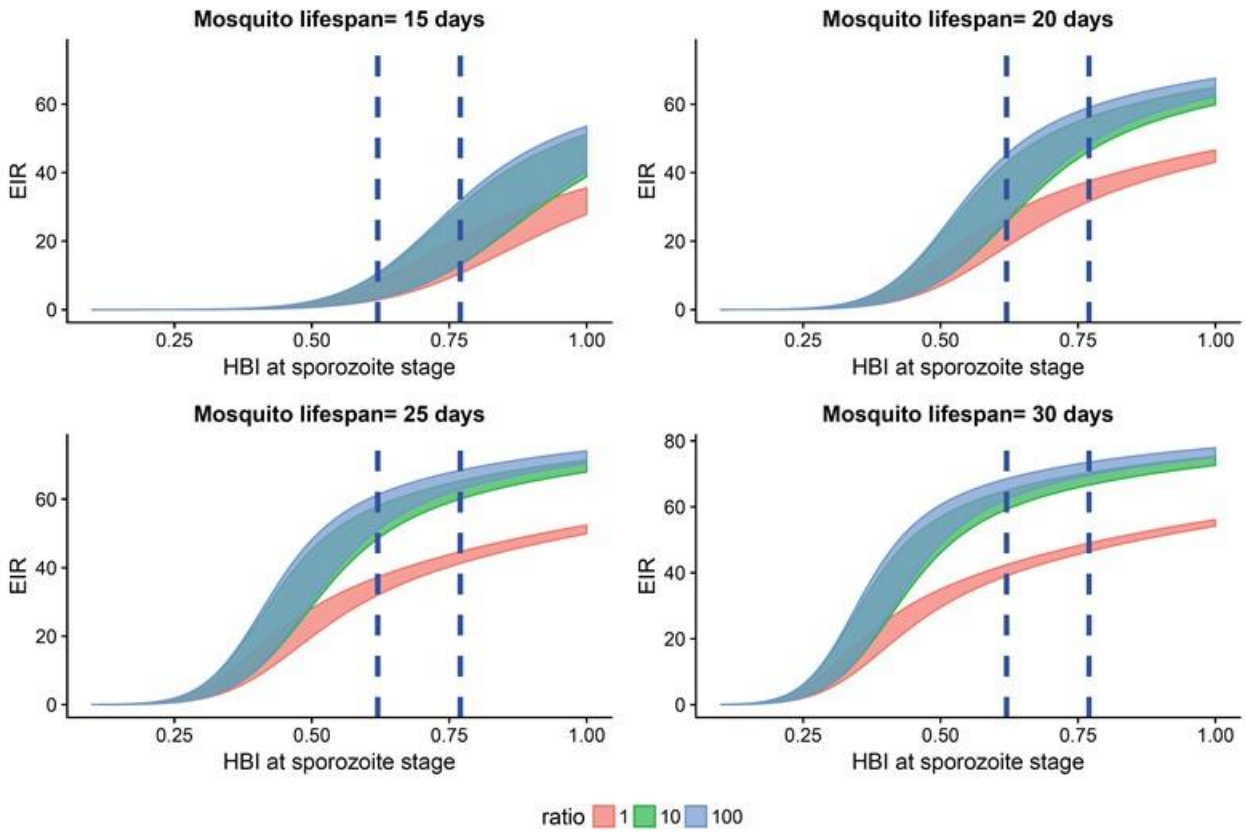

Figure 4. Expected epidemiological consequences of HBI variation for different values of mosquito lifespan and mosquito/human ratio. X axis represents the range of values considered for the HBI of infectious (sporozoite-infected) mosquitoes and the Y axis is the Entomological Inoculation Rate (EIR, number of infectious bites received by a person over one year) when the HBI of susceptible (uninfected and oocyst-infected) is 0.62. The ribbons represent the possible EIR values for different HBI of sporozoite-infected mosquitoes according to the confidence interval of HBI in oocyst-infected mosquitoes (63.6% ± 5.7%) and for different values of mosquito-to-human ratio. The dashed lines represent the value considered for susceptible mosquitoes (0.62) and the value measure for sporozoite-infected mosquitoes (0.77). Ratio=adult mosquito/human densities.

Discussion

The mosquito host preference assays (experiment 1 using OBETs and BNTs,) showed that infected mosquitoes displayed similar long-range attraction toward human odour as uninfected individuals regardless of parasite developmental stages (oocyst vs sporozoite), confirming previous laboratory results (Nguyen *et al.* 2017). However, consistent with the hypothesis of specific manipulation, the patterns of mosquito host selection (experiment 2 based on identification of mosquito blood-meal sources) showed that sporozoite-infected *An. coluzzi*, *An. gambiae* and *An. arabiensis* females were more likely to have fed on human than oocyst-infected and uninfected individuals. By distinguishing sporozoite and oocyst infection, we ruled out the potential confounding effect of a mere intrinsic mosquito characteristic. Infected mosquitoes may indeed exhibit increased anthropophagy not because of being infected but just because of an innate preference for human, thus making these mosquito individuals infected. Here, individuals infected with sporozoites displayed different HBI than individuals infected with oocysts, thus ruling out this possibility. Because *Plasmodium falciparum* takes about 10 to 18 days to complete its development (depending on temperature), there is an increased likelihood of sporozoite infection as mosquitoes become older. This means that mosquito age could be a confounding factor of infection, with infected mosquitoes displaying increased HBI not because they harbour sporozoites but because they are older. Such an age effect could be mediated by specific physiological requirements in old mosquitoes or by a positive reinforcement (learning / memory) of feeding on human. Our data does not support an age effect as we did not find a significant effect of parity (a proxy for age) on HBI (i.e. parous and nulliparous mosquito females displayed similar anthrophagy).

The precise mechanisms responsible for increased anthropophagy in sporozoite-infected mosquitoes is not yet clear, but at least three hypotheses can be proposed. First, malaria parasites might manipulate mosquito short-range behaviours only, whereas at longer range when mosquitoes rely mainly on CO_2 and other volatile odours, sporozoite-infected mosquitoes display similar preference as uninfected and oocyst-infected individuals. At short range, mosquitoes rely on other cues including visual stimuli, moist, heat and skin emanations (Takken and Verhulst 2013). These stimuli can be host-specific and informing of host suitability for parasite development before the mosquito engage in selection and eventually in feeding. In addition to a possible preferential short-range attraction of sporozoite-infected mosquitoes toward host species suitable for parasite development, there could also be short-range repellence by unsuitable host species.

Second, the parasite may induce changes in the vector such as an alteration of microhabitat choice to spatially match the habitat of the suitable host. This could be achieved through parasite manipulation of mosquito endophagic/philic behaviours resulting in a higher degree of indoor -feeding and -resting of sporozoite-infected females. For example, infectious mosquitoes may exhibit an enhanced tendency to enter (or a decreased tendency to exit) house interstices regardless of emitted odors.

Third, the parasite may induce changes in the vector such as an alteration of time activity in order to temporally match the time rest or activity of the suitable host. Mosquitoes exhibit circadian rhythms in many activities such as flight, host-seeking, swarming, egg-laying, etc. There is mounting evidence that, following bed-nets introduction, malaria vectors can display increased tendency to feed outdoors (Russell *et al.* 2011) or bite earlier in the evening or later in the morning (Moiroux *et al.* 2012). Accordingly, *P. falciparum* could manipulate

mosquito host-seeking rhythm in a way that increases bites on unprotected people. Testing this hypothesis would require sampling mosquitoes at distinct period and comparing the proportion of uninfected, oocyst-infected and sporozoite-infected vectors among samples.

Sporozoite-induced change in mosquito host selection occurred in three major and related mosquito vectors, namely *An. coluzzii*, *An. gambiae* and *An. arabiensis*. This suggests that manipulation likely already occurred in the common ancestor of these three species and that the parasites might exploit a physiological pathway common to all three mosquito species to modify its vector host choice.

Transmission models generally assume that uninfected and infected vectors have similar preference for human. This study suggests that this assumption may not be valid and that these models possibly underestimate transmission intensity. Our modelling approach confirms that HBI increase in infectious mosquitoes can have dramatic impact on disease transmission. In particular, if we consider mosquito lifespans relevant to natural settings (i.e. 15 to 20 days; Gillies 1961, Gillies and Wilkes 1965, Saul *et al.* 1990, Charlwood *et al.* 1997, Killeen *et al.* 2000), the transmission potential was almost multiplied by 3 when the HBI increased from 0.62 to 0.77 i.e. the value observed for the infectious mosquitoes in this study. For many mosquito–*Plasmodium* associations including *An. gambiae s.l.-P. falciparum*, the duration of the parasite's development within the mosquito is as long as the insect vector's average lifespan. This means that most mosquitoes do not live long enough to transmit the disease, and hence that feeds taken by infectious mosquitoes taken on unsuitable host species would have disastrous consequences for the parasite's fitness. The model suggests that the benefits of specific manipulation should be particularly high in vectorial systems in which transmission opportunities are rare (short vector lifespan, relatively long parasite development period, and diverse blood sources).

In conclusion, our results suggest that the human malaria parasite *P. falciparum* evolved the ability to enhance transmission toward human, the appropriate host species, by increasing mosquito anthropophagy (or decreasing zoophagy) with potentially profound public health consequences. Future laboratory and field studies will be essential to confirm these results and to better understand the epidemiological, ecological and evolutionary consequences of parasite manipulation of vector behaviours.

Acknowledgements

We would like to thank all volunteers for participating in this study as well as the local authorities for their support. We are very grateful to the IRSS staff in Burkina Faso for technical assistance. We thank Priscille Barreaux for discussion and comments.
